PSYCHOTIC MOTHERS

GWEN DOUGLAS
M B St And

SENIOR REGISTRAR, PORTMAN CLINIC, LONDON

NOWADAYS much emphasis is placed on the child's need, if he is to develop normally, for close relationship with an affectionate mother The work of child-guidance clinics is directed to this end, and now an effort is being made at infant welfare clinics to help mothers solve problems within themselves or their children, so that mother and baby can get on together as well as possible from the earliest days of the child's life But some women cannot benefit from such help—namely, those with postpartum psychosis

In such cases the acute psychotic episodes end fairly rapidly, but the patients tend to relapse, and the illness usually lasts for some months The consequent separation of mother from child in the child's first year of life may impair its ability to form good relationships later on

Zilboorg (1931) and Deutsch (1947) remark that postpartum psychosis is not a specific entity, but a breakdown into schizophrenic or depressive or other illness according to the patient's predisposition Nevertheless all cases have one feature in common—hostility to the baby The patient's inability to bear this hostility causes her personality to break up and earlier infantile conflicts to be brought to life so that she becomes psychotic

The old fashioned remedy in such cases was to separate mother and child, and this often proved efficacious The child was tended by a nurse or a relative, and the mother, relieved of the unbearable hostility, was more likely to recover Today suitable mother substitutes are rare Moreover, the mother who has been admitted to an observation ward or a mental hospital for treatment, though she usually recovers in hospital, commonly relapses when she is again required to care for her baby

This difficulty has been overcome in a small series of cases by admitting the baby along with its mother The husband's cooperation was sought, and the methods and aims of the treatment explained to him While the nurses undertook the physical care of the child, the mother was encouraged to do as much for the child as she felt able, and she was enabled to discuss her sentiments about this with a psychotherapist, who tried to gain the mother's confidence

Under this arrangement psychotherapy proceeded surprisingly quickly, probably because after childbirth primitive drives are strong, and thought processes which at other times are unconscious are more readily accessible Thus the patient would consider and discuss fairly readily her past relationships and attitudes to herself and others, and would accept interpretations which at another time would have been strongly resisted, and make good use of these interpretations to resolve her difficulties Once this stage was reached, the patient gradually withdrew her interest from the psychotherapeutic sessions and transferred it to her baby

Thus the mother got to know the baby at her own pace, and had the daily reassurance that, despite all her own strange mixed feelings towards her infant, it still survived with the detached physical attention given by the nurses As her fear of her own negative feelings to the child lessened she gained more confidence to undertake its physical care, but she was not detached, for she felt that she could give her baby more than anybody else She could then become, as Dr D W Winnicott has put it, "an ordinary devoted mother"

Of the following four cases, the first two illustrate the tendency to relapse when full care of the baby is undertaken before the patient is ready for this, and the last two show how such relapses can be avoided

Case-records

Case 1 was a pretty, intelligent young woman, married to a man much older than herself on whom she could rely for security Being the youngest of a large family she had been pampered and treated as the delicate one She had always suffered from many minor ailments, including palpitations for which no organic cause could be found After three years of marriage the patient became pregnant She was well throughout pregnancy but towards the end was worried as to whether she would be able to care for the baby adequately

She was not noticed to be abnormal during the puerperium, but she felt very inadequate when she got home With much support from relatives she managed until the baby was 5 months old, when she became more tense and strained, then expressed delusional ideas, believing without reason that a film had been made about her and that other people were wearing her clothes and impersonating her She became withdrawn, and had to be admitted to an observation ward

Over the next two weeks the patient gradually became more in touch with reality When she was able to talk about her illness she admitted having felt depressed and inadequate since the birth of her child, she said that this was because her relatives had done too much for her, and she was over confident that she would remain well She was perplexed about her state of mind immediately before her admission to hospital, and could give no clear account of it She insisted on going home and taking full responsibility for her baby

When seen at the outpatient clinic the following week she was again withdrawn. She sat staring in front of her, she was disorientated in time and spoke off the point, saying such things as "are you going to bury me, is my baby dead?" Yet again she made a rapid superficial recovery in the observation ward, but in view of the previous failure to maintain improvement she was persuaded to enter a mental hospital as a voluntary patient

There she was given a course of deep insulin therapy with electroconvulsion therapy (E C T) in sopor towards the end of the course Schizophrenia with hysterical features was diagnosed at the mental hospital where the prognosis was regarded as not very favourable She left against advice after three and a half months

On returning home she once more tried to look after her child, this time succeeding for several weeks until she became as seriously disturbed as before, so that it was necessary for her to be admitted to the observation ward yet again This time, with the agreement of the superintendent of the mental hospital in which the patient had recently been, she was admitted to the neurosis ward of the general hospital with her baby also in hospital, and was treated by psychotherapy and gradually undertook the care of her baby She made a good recovery, and was discharged home after three months She has remained well and has cared for her child in the subsequent two years

Case 2 was the youngest of several children The mother died when the patient was 3 years old, so she was brought up by her father and an older sister She was considered a fairly normal child but did not mix well with children of her own age When she first became engaged to be married, and again just before her marriage, she had a "nervous breakdown" for which she received treatment at home, and she recovered She was strongly attached to her father Her husband was an immature young man who could lend the patient little emotional support They both wanted the baby

While in hospital when the child was 5 days old, the patient suddenly made a suicidal attempt She tried to throw herself out of a window, but was forcibly restrained by a nurse She was deeply depressed, and she was also deluded, believing that her husband had deserted her (whereas he was visiting her regularly), and that she was to be sent to prison for all the wrong that she had done On account of persistent suicidal intention, she had to go to a mental hospital under certificate

A course of E C T led to a good recovery, and she was discharged home to look after her baby, but two weeks later she was admitted to an observation ward again She made a rapid superficial recovery On her discharge the baby was put with foster parents and the patient got a job, where she seemed quite

OBSERVATIONS ON RATS RECEIVING δ-AMINOLÆVULIC ACID OR PORPHOBILINOGEN WITH AND WITHOUT EXPOSURE TO ULTRAVIOLET RADIATION

Treatment (dose of drug 30 mg per kg of body-weight)	Symptoms	Ultraviolet fluorescence		Skin histology	Urine (24 hours)
		Skin (frozen sections)	Intestines		
δ Aminolævulic acid and ultraviolet irradiation	Irritability hyperæmia of skin	+ + + In stratum corneum	+ + +	Subepidermal blisters infiltration (fig 1)	
δ-Aminolævulic acid without irradiation	Nil	+ + In stratum corneum	+ +	Normal (fig 2)	Coproporphyrin 1 6 µg protoporphyrin 0 16 µg uroporphyrin 0 24 µg porphobilinogen ? trace
Porphobilinogen and ultraviolet irradiation	Nil	+ In stratum corneum	+ +	Normal (figs 3 and 4) one selected area shows collagen damage and infiltration (fig 4)	Corproporphyrin 0 48 µg protoporphyrin 0 10 µg uroporphyrin 17 2 µg porphobilinogen + +
Ultraviolet irradiation only	Nil	? Trace	+	Normal (fig 5)	

porphyria The important observation has, however, been made, in a self-experiment by Dr Scott, that its ingestion *is followed by transitory hypersensitivity to* sunlight (Berlin et al 1954a and b, Scott 1955)

Granick and Vanden Schrieck (1955) injected δ aminolævulic acid 130 mg per kg body weight into a white rat intraperitoneally and observed no symptoms of distress The rat's urine next day contained a little zinc porphyrin complex, but the contents of the stomach and duodenum, and the femoral bone marrow fluoresced strongly in ultraviolet rays

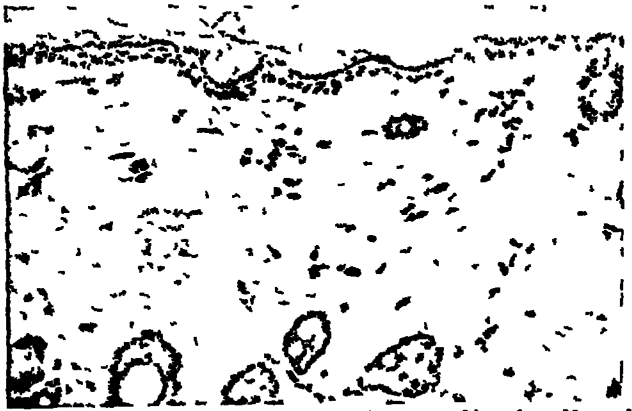

Fig 2—Skin of rat receiving δ-aminolævulic acid only Normal histology (Hæmatoxylin and eosin ×160)

Investigation

We have compared the effects of subcutaneously administered δ aminolævulic acid and porphobilinogen on albino rats with and without exposure to the radiation from a small carbon arc The animals were shaved on the back and sides, and 10 minutes after an injection (30 mg per kg body-weight) were exposed, with shaved *but uninjected controls for 15 minutes at 12 inches* distance There was no overheating under these conditions

The control rat and the rat injected with porphobilinogen showed neither irritability nor hyperæmia, but the rat injected with δ aminolævulic acid and irradiated showed definite signs of irritability, such as scratching, biting, and shaking itself—movements which continued for some time after removal to the cage—and its skin was hyperæmic The rat given the same dose of δ aminolævulic acid but not exposed to ultraviolet rays appeared perfectly normal

All the rats were killed after 24 hours, and portions of their *skins were fixed, sectioned, and stained or* examined immediately (frozen sections) by ultraviolet fluorescence microscopy The thorax and abdomen were also opened in each rat for macroscopic examination under ultraviolet rays The findings are listed in the accompanying table, and the histological changes in the skin are recorded in figs 1–5

Discussion

A considerable amount of porphyrin is formed from both δ aminolævulic acid and porphobilinogen, the greater part being eliminated via the bile into the intestine (Granick and Vanden Schrieck 1955, Scott 1955) The comparatively large quantity of uroporphyrin in the urine of the rat given porphobilinogen may have been derived non enzymically (Cookson and Rimington 1954) from porphobilinogen, which was also present in the urine Only the combined treatment with δ aminolævulic acid and irradiation caused photosensitivity, and fluorescence due to porphyrin was more intense in this rat than in the one not exposed to the arc-light The difference in fluorescence was greatest in

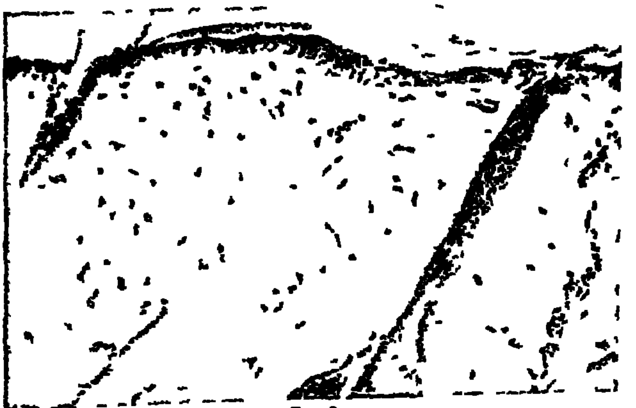

Fig 3

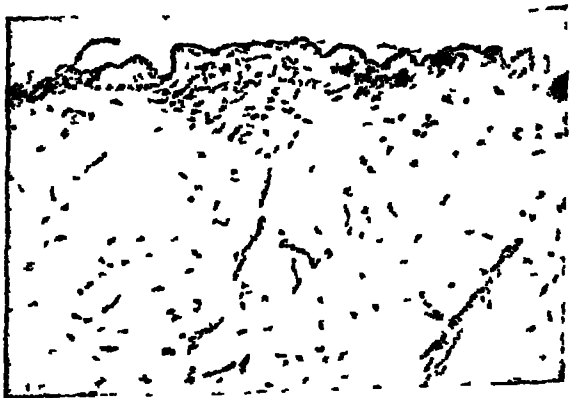

Fig 4

Figs 3 and 4—Skin of rat receiving porphobilinogen and ultraviolet radiation Histology generally normal (fig 3), but occasional affected areas (fig 4) with minor collagen damage and some infiltration (Hæmatoxylin and eosin ×160)

there was no abnormality of sensation Chvostek s and Trousseau s signs were negative The temperature was 99 8°F, the heart-rate 100 per min, and the blood pressure (which had never been measured before) 130/95 mm Hg She had diarrhœa and was incontinent of urine The diarrhœa continued in hospital for only four days, during the last two of which chloramphenicol was given No pathogenic organisms were cultured from the stool

Investigations

In the serum the level of potassium was 1 7, of sodium 147, of chloride 104, and of bicarbonate 29 m eq per litre The electrocardiogram showed evidence of potassium deficiency

Treatment and Progress

Potassium acetate was given by mouth, about 90 m eq being administered in the first sixteen hours Since there was no increase in muscle power or in potassium level the rate of administration was increased to about 250 m eq per twenty-four hours Muscle power then improved but was not normal until four days later On the sixth day, when the potassium level in the serum was 6 5 m eq per litre, the potassium was discontinued by this time she was taking food

On the third day she complained of pins and needles in the fingers and toes, and was found to have latent tetany, this continued for almost forty eight hours

The urine contained a trace of protein and was nearly neutral (pH 6 7–7 1), the highest specific gravity after eighteen hours' water deprivation and injection of 5 ml of 'Pitressin' was only 1 010 The centrifuged deposit contained a few white blood cells, but cultures were sterile The blood-urea was 82 mg per 100 ml on admission, and 72 mg per 100 ml two weeks later Seven months later it was 40 mg per 100 ml

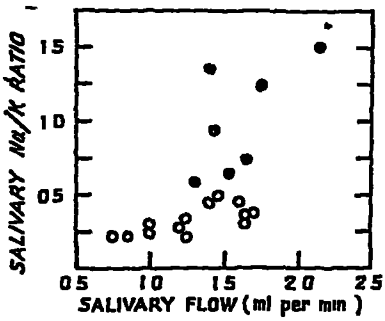

Fig 1—Salivary sodium/potassium ratios plotted against rate of salivary flow Open circles represent preoperative samples black circles postoperative samples

Renal conservation of potassium was defective During an eleven-day period when the level of potassium in serum varied between 1 7 and 2 1 m eq per litre, the mean daily output of potassium in the urine was over 70 m eq During a five-day period in which the patient was given ammonium chloride (115 m eq per day) the urine pH fell to 5 1, and the urinary content of titratable acid minus bicarbonate rose from −9 to +23 m eq per day, and of ammonium from 36 to 119 m eq per day

The patient remained well from the fifth day in hospital She was discharged after a stay of six weeks After discharge she took 80 m eq of potassium chloride daily, and said that she felt better than she had for some years, but the thirst continued

When the dehydration and electrolyte depletion had been corrected her blood pressure had risen, and it varied between 160/90 and 230/120 mm Hg During the twelve months between discharge and her second admission she continued to be hypertensive, the highest recorded pressure being 220/150 mm Hg

Second Admission

In April 1955, the patient was readmitted for further study as a possible case of Conn's syndrome Her blood pressure was 225/140 mm Hg with 20 mm of pulsus alternans, triple rhythm was heard, and radiography showed enlargement of the heart, the fundi were normal Although the blood pressure fell slightly during her stay in hospital (fig 5) it continued to be high, and when after a short time at home she was readmitted on June 8 for operation, it was 205/130 mm Hg

To show whether the patient had a tumour secreting salt retaining hormone, three main lines of investigation were followed

Salivary sodium and potassium levels—Conn (1955a) suggested that a low ratio of sodium to potassium in saliva and sweat indicated increased activity of salt retaining hormone, it was largely this finding that led him to postulate such increased activity as the cause of the electrolyte abnormality in his patient, since it showed that the abnormality of excretion was not confined to the kidney In our patient this ratio was found to be low (fig 1)

TABLE I—CORTISOL AND ALDOSTERONE LEVELS IN BLOOD AND URINE

Date (1955)	Specimen	Cortisol in whole blood or 24 hr urine (µg per 100 ml)	Aldosterone in whole blood or 24 hr urine (µg per 100 ml)
Jan 20	Blood	2 7	<0 1
May 4	Blood	4 2	<0 1
March 8–9	Urine	40	8
May 4–5	Urine	35	11
May 5–12	Urine	21	28
June 10		Operation	
Sept 25–26	Urine	8 7	1 1

Assays of *aldosterone in the blood and in the urine* were made by Mrs S A Simpson and Dr J F Tait at the Middlesex Hospital Medical School, who reported as follows "The blood was extracted at neutral pH Cortisol (hydrocortisone) and aldosterone were fractionated and estimated as described in detail previously (Simpson and Tait 1955) The urine was continuously extracted at pH 1 with chloroform for 24 hours at room temperature and the resulting free cortisol and aldosterone purified by column chromatography The aldosterone was measured by bio assay at this stage Aldosterone diacetate and cortisol monoacetate were also prepared from this fraction and, after purification, estimated by the soda fluorescence method (Bush 1952) A detailed description of the methods will be submitted for publication elsewhere

" The aldosterone and cortisol were analysed in a 200 ml sample of blood collected at 9 30 A M on Jan 20, 1955, and May 4, a 24 hour specimen of urine on March 8–9 and May 4–5, and in a 7 day bulked collection of urine between May 5 and 12 The results, together with those in a postoperative specimen of urine taken on Sept 25–26, are shown in table I The values for aldosterone using the bio assay procedure showed good agreement with those found by the physico chemical method within the limits of experimental error

" The mean value for cortisol in peripheral blood collected at 9 30 A M from normal males determined by the method used in the present investigation has been found to be 2 7 µg per 100 ml whole blood, with a range of 0 5–4 7 µg for eleven individual determinations a pooled specimen from twenty volunteers gave a value of 2 5 µg per 100 ml The mean value for aldosterone from the same subjects was 0 08 µg per 100 ml The mean value of the amount of cortisol in urine collected from six male patients not suffering from any obvious endocrine disease has been found to be 43 µg per 24 hours, with a range of 23–57, and that of aldosterone in the same urine 12 µg per 24 hours with a range of 8–16 Thus only the pooled urine

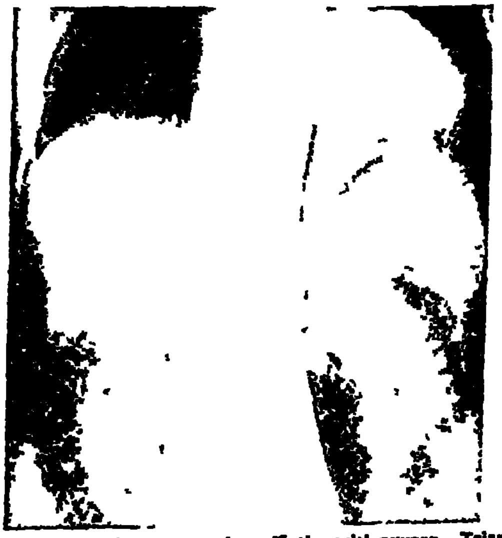

Fig 2—Tomogram after presacral insufflation with oxygen Triangular shadow above each kidney is cast by adrenal Round tumour is seen at apex of right adrenal

successful stand against his illegal dismissal from a government post

He graduated from Yale in 1908 and took his M D at Columbia College of Physicians and Surgeons in 1913 While holding an appointment at the Presbyterian Hospital in New York he served as instructor in clinical medicine at the college In 1917, with a research fellowship, he moved to the Russell Sage Institute of Pathology In 1921 he went to Yale as an associate professor of medicine, and he was elected to his chair in 1927

As the senior professor of medicine at Yale he took an important part in the movement for development of the public-health services, and he was a consultant to the United States Public Health Service on Federal grants for medical research Another of his advisory appointments was that of consultant to the Surgeon-General of the United States Army It was against his dismissal from this appointment on grounds of disloyalty that he successfully appealed in the Supreme Court last June

Of his scientific work one of his English colleagues writes

In his preface to the first, and alas only, volume of the second edition of what is known formally as *Quantitative Clinical Chemistry*, but familiarly as *Peters and Van Slyke*, Dr Peters remarked " When the task of writing the book was first undertaken, clinical chemistry was adolescent " The book was published in 1931, and ever since has been the standard reference in its subject In the progress of clinical chemistry from adolescence to maturity, no one has contributed more than Peters himself, and in the year of his death further notable contributions appeared from him and from his school He was perhaps specially concerned with water and electrolyte metabolism, his book on *Body Water* (1935) is a classic, and he has since reviewed this explosively expanding subject in *Physiological Reviews* and in successive editions of *Duncan's Diseases of Metabolism* Even before 1920 he and his group had published many important original papers on œdema, renal disease, and lipide metabolism His was perhaps specially notable for the equal stress which he laid on the clinical and chemical work in his unit, his young men were trained both to look after their patients and to carry out their own chemical estimations, and neither duty could be scamped or delegated Even when official duties and advisory work claimed much of his time, they could not submerge his originality

Notes and News

TEACHING HOSPITAL IN THE WEST INDIES

THE Secretary of State for the Colonies has appointed a committee with the following terms of reference

> " To inquire into the financial needs and methods of financing of the University College of the West Indies Teaching Hospital to make proposals for its essential capital and recurrent requirements in relation to the financial resources available and to assess the proportion of the cost arising from the teaching functions of the hospital "

The chairman of the committee is Dr R S Aitken, vice-chancellor of the University of Birmingham, and the other members are Dr E R Boland, dean of Guy's Hospital Medical School, Dr J W P Harkness, medical adviser, Development and Welfare Organisation, West Indies, and Mr G A Phalp, secretary of the United Birmingham Hospitals' Board

WELLCOME TRUST

GRANTS made lately by the Wellcome trustees include £25,000 to the Medical Research Council towards the cost of an investigation of trachoma to be carried out in Jordan and London under Sir Stewart Duke Elder The trustees have also allocated up to £33,000 for the purchase of three electron microscopes for indefinite loan to the Medical Research Council (for use initially in the department of biophysics at University College, London), to the physiological laboratory, University of Cambridge, and to the department of human anatomy, University of Oxford

PROGNOSIS IN ESSENTIAL HYPERTENSION

THE prognosis when essential hypertension is discovered in patients under 46 has been studied by Storm Mathisen in the University Clinic, Oslo[1] Hypertension (defined as a systolic blood-pressure of 160 mm Hg or more, and a diastolic blood-pressure of 95 mm Hg or more) was found for the first time in 290 patients (111 men and 179 women) who were in hospital with other illnesses, the mean age of the men was 37 and of the women 38 When these patients were recalled for examination ten years later (in 1950–51) 46 men (42%) and 52 women (29%) had died, the great majority from their hypertension Their average survival after the discovery of their hypertension was five years It was noteworthy, however, that the 97 cases in which the diastolic pressure sometimes fell below 95 mm Hg had a mortality of 8%, which compares very favourably with the 43% mortality of those whose diastolic pressure was not observed to fall below that level For the whole group of 290 patients, the death rate in men was more than eleven times, and in women more than seven times, greater than for the general population, but the death rate for patients with a diastolic pressure which sometimes fell below 95 was of the same order as for the general population.

Among the causes of death coronary thrombosis was uncommon, and though Storm Mathisen admits that this may be explained partly by the patients being young, he thinks that there would have been more such deaths if, in fact essential hypertension predisposes to coronary thrombosis

JOURNAL OF ANALYTICAL PSYCHOLOGY

THE first issue of this journal,[2] published on behalf of the Society of Analytical Psychology in London, is dedicated to Prof C G Jung and forms part of a specially bound volume presented to him by the society on the occasion of his 80th birthday A preface by Dr Michael Fordham, the editor, explains that the journal has been launched in order to afford an outlet for work by the growing body of analytical psychologists in this country, and not only to increase the influence of analytical psychology The editor is assisted by four distinguished British analysts and has secured the collaboration abroad of several eminent analytical psychologists The quality of this first issue augurs well for the journal's future development

TABLE II—RENAL CLEARANCES (EACH THE MEAN OF THREE PERIODS)

Date	Inulin (ml per min)	*p* amino hippurate (ml per min)	Filtration fraction	Potassium/inulin ratio
Before operation				
June 11, 1954	41 5	220	0 20	1 16
May 16, 1955	49 2	267	0 184	
After operation				
July 12, 1955	29 0	156	0 19	0 4

Hg There was a gap in the preoperative observations because she spent some days at home During the operation there were no large variations in blood-pressure, although it rose slightly while the adrenal was being handled Two days later the pressure was 160/90 mm Hg, and it fell further as time passed (fig 5) More recently higher readings have been obtained, the pressure at her latest follow up visit, on Oct 20, was 156/110 mm Hg A radiograph of the chest thirty one days after operation showed a reduction in the size of the heart and aortic knuckle the transverse diameter of the heart shadow twenty-two days before operation was 145 mm, and thirty one days after operation 130 mm

Heat elimination from the hand, at complete release of vaso constrictor tone achieved by warming, was measured in the right hand on two separate occasions before operation by a modification of the method described by Stewart (1911) The determination was repeated in the same hand under the same conditions after operation The heat elimination was normal preoperatively, and did not fall significantly despite the fall in blood pressure

The *renal clearances of inulin and* p *aminohippurate* were measured on two occasions before operation and again thirty two days afterwards (table II) The first two readings, which agree well, show subnormal function The postoperative determinations show much deterioration, which is reflected also in the serum urea level, which was 68 mg per 100 ml at this time, and which remained at about this level three months after operation The lowering of the clearances is approximately proportional to the lowering of the blood-pressure

The preoperative *clearance of potassium* exceeded that of inulin, although the concentration of potassium in the serum was only 1 9 m eq per litre From this finding, and because of the continued suppression of hydrogen ion excretion, tubular hypersecretion of potassium was presumed to be occurring After operation the ratio of the potassium clearance to the inulin clearance fell to 0 4 and the urine became acid (random pH 5 6)

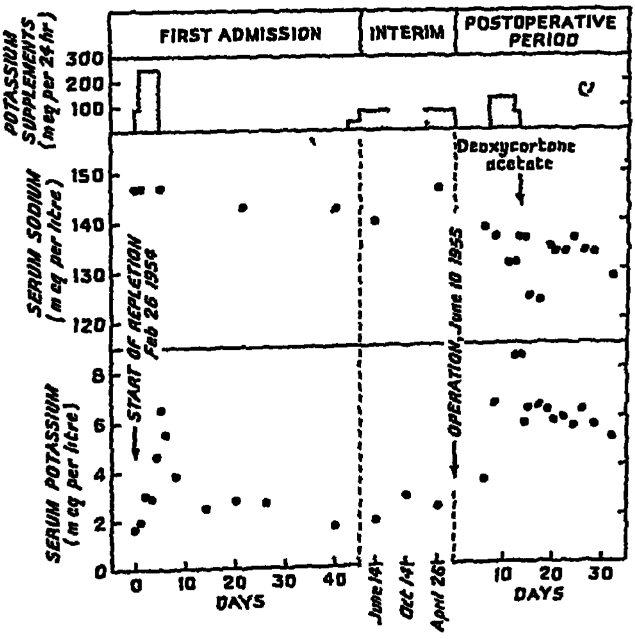

Fig 6—Levels of sodium and potassium in serum throughout period of treatment

The *salivary sodium/potassium ratio* rose greatly after operation (fig 1) To show that the difference is not due to an increase in salivary flow (Garrod et al 1955) the ratios have been plotted against rates of flow

The levels of *sodium and potassium in serum* during the whole period of treatment are shown in fig 6 Four of the seven preoperative sodium values are unusually high (147 m eq per litre) The fourteen values since operation were between 124 and 139 m eq per litre The preoperative potassium concentration, initially low, rose rapidly to a high level (6 5 m eq per litre) on a potassium supplement of 250 m eq per day On a normal diet without supplement it fell to the previous level after thirty five days, and was maintained between 1 9 and 2 9 m eq per litre on a supplement of 80 m eq daily After operation the level rose to 6 5, and, when potassium was added to the diet, to 8 5 m eq per litre At this point 5 mg of deoxycortone acetate was given The level has since remained between 6 5 and 5 2 m eq per litre without supplement

The *serum chloride* level was normal throughout, except on the fifteenth postoperative day when it fell to 94 m eq per litre in keeping with the low sodium level at that time The serum level of *total carbon dioxide* was usually normal, but one value of 32 m mol per litre was observed, and on another occasion the pH of a sample of arterial blood was 7 47

TABLE III—RESULTS OF ISOTOPE DILUTION

Date	Body wt (kg)	Exchangeable Na		Exchangeable K		Remarks
		m eq	m eq per kg	*m eq*	m eq per kg	
March 10, 1954	45 4	2150	47 4	1785	39 3	After repletion
April 7, 1954	44 6	2409	54 0	1441	32 3	After further depletion
June 15, 1954	50 0	2065	41 3	1608	32 2	On supplement
May 18, 1955	55 9			1655	29 6	On supplement
May 20, 1955	55 9	2600	46 5			
June 10, 1955						Operation
July 6 1955	55 0			2088	38 0	
July 8, 1955	55 0	1893	34 4			

The amount of *electrolyte in the tissues* was determined by three methods isotope dilution, analysis of muscle, and measurement of the electrolyte balance The total exchangeable sodium and potassium were determined, usually simultaneously, by a modification of the method of James et al (1954) The results (table III) are expressed both absolutely and in relation to body weight Increases in body sodium were accompanied by decreases in body potassium, and vice versa The first determination, made after the initial repletion with large amounts of potassium, gave values which were within normal limits, although, because of variations in the total mass of muscle and fat, these limits are wide and difficult to define Thereafter, until operation, the content of potassium was low, the content of sodium on April 7, 1954, when the patient had been without a potassium supplement for some weeks, was above normal After operation the most obvious change was a fall in the sodium content of 707 m eq from the last preoperative figure, the potassium content having increased by 433 m eq in the same time These changes are consistent with the hypothesis that the tumour was exerting a salt retaining, potassium losing effect

Also consistent with this hypothesis are the results (table IV) of analysis of the specimen of muscle removed at operation Normal values (Mokotoff et al 1952) are given for comparison

Balance measurements were made during two phases of the patient's illness first, from the time of admission until eighteen days later (during the first six days of this period large doses of potassium were given), and second, during the thirty days immediately after removal of the tumour In the first period there was a net gain of potassium of 767 m eq during the six days for which it was administered, when the supplement was stopped about 200 m eq was lost before approximate equilibrium was established Sodium was lost in excess of chloride during the phase of potassium loading later both sodium and chloride were retained On the assumption that chloride did not enter or leave cells intracellular sodium decreased by 500 m eq while intracellular potassium increased by 639 m eq over the eighteen day period Potassium entered the cells rapidly, but sodium was discharged

ORTHODOXY AND HETERODOXY II*

Sir HENEAGE OGILVIE
K B E , M A , M Ch Oxfd, F R C S ,
Hon F R C S C , Hon F R A C S , Hon F A C S
CONSULTING SURGEON TO GUY'S HOSPITAL

A QUARTER of a century ago I was invited to Chichester to read a paper on Orthodoxy and Heterodoxy in Surgery This was the first time that I had been asked to speak to a medical society It was the first time I had attempted to tackle an essay type of subject, and in this sense the invitation was a decisive event in my career Now I come again after twenty-five years to the same city to speak to the same society on the same subject My talk must therefore fall into two sections first, a re examination of my previous views on orthodoxy in the light of greater experience, and secondly a review of the verdict of history on the orthodoxies and heterodoxies of those far off days

Virtues of Orthodoxy

I pointed out then that a fundamental problem in all institutions is how to combine security with progress, tradition with discovery Security without progress means stagnation and decay, progress without security leads to anarchy and ruin

Orthodoxy means the holding of right or accepted views in matters of public interest The personal affairs of an individual are his own concern, but in matters affecting the many, a general standard of orthodoxy is necessary, indeed inevitable, from which standard any departures are judged Orthodoxy is the sifted and codified view of the majority When we say that a thing is orthodox, we mean that it is the belief of the majority, but not necessarily that we agree with it

Orthodoxy therefore represents the wisdom and learning of the past, and it provides the security of that wisdom An orthodox novelist, scientist, or doctor can be trusted to have as much learning as the last generation of his craft That may seem a small commendation, but it is in fact one of fundamental importance, because where there is no body of orthodoxy there is no assurance to the public that the specialist in any branch of learning knows anything at all A man may set himself up as a surgeon, a preacher, an engineer, or an architect without knowing as much of these arts as an African witch-doctor

This is the value, in surgery, of orthodoxy, and of the machinery of examinations, degrees, and corporations that upholds it It ensures that the surgeon does, at any rate, know something of his job The public has no assurance other than the label provided by the degree—a degree granted by a committee of the orthodox for a knowledge of orthodox practice—that they are entrusting their lives to someone who is not an ignoramus Without such a guarantee the sick man is indeed in a quandary One friend tells him to go to So and so, another to some one else, and he has no better reason than their opinion to guide him in his choice He has no better reason, for nothing better exists He has no expert knowledge himself to enable him to judge between the claims of rival hucksters, and, in the absence of orthodoxy, he would not even know where to acquire that knowledge He is likely to be swindled by teachers as ignorant as himself This is no fanciful picture This was the lot of the sick man throughout the world not many years ago It is the lot of the sick in many parts of the world today It is the lot even in this country of people who, when they are sick, spurn orthodoxy because they know better

Orthodoxy then is the essential basis of civilisation, and the real difficulty is to prevent orthodoxy passing into stagnation, to devise machinery for discarding theories that have ceased to accord with modern views, and practices that have ceased to have value, in short, for ensuring that the heterodox is heard, tested, and, if approved admitted to the body of the orthodox

Authority and Inquiry

The more ancient and stable is a civilisation, the more securely does orthodoxy become enthroned, because the more certainly does authority pass into the hands of the elderly The elderly, who have experienced life's troubles and sifted life's problems, and arrived in the end at an explanation that satisfies them and a modus operandi that works, are usually sure that their conclusions are the right ones, and that any new ideas presented to them are a revival in different guise of the doubts and questionings that disturbed them when they were young The teachings of medicine have always tended to be authoritative The word of Galen was law for more than a thousand years, and any attempt even to question his pronouncements was looked on as dangerous ignorance The Renaissance brought a new spirit of inquiry, but resistance to the new remained Darwin's teachings, humbly though they were propounded, were opposed not merely by the Church but by most scientists Lister's views on the causation of sepsis were scoffed at and his treatment was opposed by the majority of surgeons, and only at Guy's were they received immediately and enthusiastically Like many revolutionaries, Lister in turn became a pillar of the new orthodoxy he had created, and an opponent of the aseptic surgery that his followers were shaping

When I spoke in 1930, I was speaking, though I [illegible] not know it, in terms of a phase of the world's [illegible] that was even then passing away I spoke of "[illegible] tongue tied by authority, and folly doctor-li[illegible] con trolling skill," and of the need to fight for freedom [illegible] per rule of authority received its death blow in the first w[illegible] war, and was even then passing away, at any rates [illegible] countries outside the Iron Curtain Now we ha[illegible] reverse outlook In place of "look before you [illegible] have the maxim "try anything once" In pla[illegible] man of learning we worship the revolutionary We [illegible] displaced the Apollo Belvedere from our art galleries, a[illegible] put in his place a wire puzzle dedicated to the Unknown Political Prisoner

The spirit of inquiry is admirable if it is really inquiry and not uncritical novelty worship It is right that we should examine and consider every new thing that is presented to us, but not necessarily right that we should adopt it Most new things turn out in the end to be wrong When presented with a new project for acceptance, we should first ask "Is it reasonable?" Then, "Is it really new? Has it, or anything like it, been tried before? If so, has it failed, and why? Was the failure due to some inherent defect, or to some circumstances that can now be remedied? If it is reasonable but yet untried, can it be tried without risk? If there is a risk, how can that risk be eliminated or minimised? Are we justified in a full scale trial, or should we first try a pilot experiment? Can the experiment be done first on ourselves?"

Experimentation with the lives of others is as tempting to the rash surgeon as experimentation with the property of others is to the rash politician In each case success means personal credit, failure means a loss to someone else The worst examples of rash enterprise are seen in politics, for the politician must fire off all his rockets before the next election and he seldom has the time for careful consideration or for pilot experiments There has been in surgery no example of foolish enterprise and blindfold experiment comparable to the Ground Nut Scheme in East Africa The idea was magnificent, but

* Read before the Chichester and District Hospitals Clinical Society on Oct 12, 1955

6908

pressure, are presumably due to a fall in perfusion pressure, the vascular resistance of the kidney remaining unchanged. The clearances behave similarly during reduction of the blood-pressure by various drugs (Freis et al 1953). Thorn et al (1952) found such changes after sustained falls in the blood pressure of hypertensives brought about by total adrenalectomy; the reduction in glomerular-filtration rate and renal blood-flow was greatest in those patients whose blood-pressures were lowered the most.

It is now well known that chronic potassium depletion can lead to a characteristic nephropathy, in which vacuolation and degeneration of tubular epithelium are associated with impaired capacity for urinary concentration and acidification, and with lowered glomerular-filtration rate and *p* aminohippurate clearance (Schwartz and Relman 1953, Relman and Schwartz 1955). All these features were present in some degree in our patient, although the impairment of acidification was slight (cf Clarke et al 1955). The results of nephron dissection show that the structural changes were almost confined to the proximal tubule. In some of Schwartz and Relman's cases slow recovery followed repair of the potassium deficit.

Summary

A patient with recurrent paralysis due to excessive urinary loss of potassium, and with hypertension, is described.

Alkalosis was slight or (more often) absent. Urinary concentrating power was lost, but the capacity for urinary acidification was only slightly impaired.

A tumour of the right adrenal gland was demonstrated radiographically, and its removal reversed the electrolyte abnormality and lowered the blood-pressure.

Urinary excretion of aldosterone was normal or only slightly increased, but fell after operation. Blood-aldosterone levels were within normal limits.

Renal biopsy showed vacuolation of the tubular epithelium almost entirely confined to the proximal tubule, with minimal changes in the distal tubule.

Isotope dilution and muscle analysis showed that the patient's tissues contained more sodium and less potassium than normal; operation ultimately reversed these changes, but balance data showed that sodium retention occurred for a short time after operation.

Renal clearances of inulin and *p* aminohippurate, initially low, were further reduced after operation, approximately in proportion to the reduction of blood pressure.

We are much indebted to those colleagues named in the text, and to Dr O Garrod, who have been concerned in the investigation or treatment of this patient, and who have allowed us to quote their findings. We also acknowledge gratefully the help of Dr Paul Fourman and the technical assistance of Mr Emlyn Morgan. One of us (M G T) held a Cardiff Royal Infirmary research fellowship in medicine.

PLASMA FIBRINOLYTIC ACTIVITY IN CIRRHOSIS OF THE LIVER

H C Kwaan
M B Hong Kong
SENIOR CLINICAL ASSISTANT
A J S McFadzean
M B Glasg, M R C P
PROFESSOR OF MEDICINE
J Cook
F R C S E, F A C S, D P H
SURGICAL SPECIALIST
From the University Department of Medicine and Queen Mary Hospital, Hong Kong

A PROTEOLYTIC enzyme is present in normal blood in the form of an inactive precursor, plasminogen, which is associated with the globulin fraction. An inhibitor, antiplasmin, is present in excess in the albumin fraction. Plasmin activity can be produced by streptokinase, which activates plasminogen; by chloroform, which destroys antiplasmin; and by techniques such as fractionation of the plasma which separates the plasmin-antiplasmin complex (Macfarlane and Biggs 1948). Plasmin not only produces fibrinolysis but also digests plasma-proteins (including fibrinogen), casein, and gelatin.

Goodpasture (1914) first reported spontaneous fibrinolysis in cirrhosis of the liver: the clotted plasma obtained from 3 cases liquefied when incubated at 37°C for sixteen hours. He added a 4th case, but in this the plasma was obtained after death. In contrast he found that the blood clots of healthy controls remained unlysed for many days.

Since then spontaneous fibrinolysis has been found in various diseases. It has been observed in patients who have undergone surgical operations (Macfarlane 1937), and according to Ratnoff (1952) Fantl and Simon described its occurrence during electric shock therapy. It has been induced in healthy people by the injection of adrenaline and by severe exercise (Biggs et al 1947).

It has been assumed in the past that spontaneous or induced fibrinolytic activity in the plasma was due to plasmin, but according to Biggs and Macfarlane (1953) Fantl and Simon showed that the fibrinolysin found in the blood of rats subjected to electrical convulsions had no effect on fibrinogen. Bidwell and Macfarlane (1951) noted similarly that the fibrinolysin found in the blood of man after severe exercise had no effect on fibrinogen. They also showed that this fibrinolytic activity was not influenced by the serum inhibitor of plasmin. Biggs and Macfarlane (1953) considered that either the naturally activated factor was not plasmin or, if it was, its action was considerably modified.

Uncontrollable hæmorrhage from multiple sites associated with extreme fibrinolytic activity of the plasma after splenectomy in a patient with cirrhosis of the liver directed our attention to this problem. We report here our observations on the incidence and intensity of spontaneous fibrinolytic activity of the plasma in cirrhosis of the liver and the influence of surgical trauma thereon.

Material and Methods

Observations were made on 30 consecutive cases of cirrhosis of the liver, and on 12 consecutive cases of

Results

Chlorpromazine 1 mg per kg body-weight intravenously abolished "spontaneous" tetanus (i e no intended afferent stimuli applied) and reflex tetanus for 77 min (mean of 7 experiments) The minimum time was 27 min, and the maximum 120 min During this time the animal did not respond with muscle spasm to the standard afferent stimulus, which before the drug was given produced a pronounced increase in spasm (fig 1) If no afferent stimulus was applied the tetanus was abolished for periods up to twice as long Larger doses of chlorpromazine abolished reflex tetanus for up to 4 hours

The animals were quiescent after chlorpromazine 1 mg per kg body-weight, but normal rabbits given this dose would hop about if encouraged Respiration was unaffected

Control injections of saline did not reduce the tetanus

Promethazine also abolished tetanus, but only in high dosage (4 mg per kg body-weight) and for a shorter time (less than 1 hour)

With these results in mind it was felt justifiable to attempt to control human tetanus convulsions with chlorpromazine alone, for spontaneous respiration and retained consciousness might be of very great advantage, whereas unconsciousness, with or without neuromuscular block, prolonged for many days and possibly even weeks, could not but influence the patient unfavourably

Case-report

A boy, aged $2^1/_2$ years, crushed the tip of a finger in a door on Aug 25, 1955, and was taken to hospital No tetanus antitoxin was given He was later transferred to the plastic unit at Mount Vernon Hospital, where he underwent a repair operation on the same day

On Sept 6 his mother noticed that he could not open his mouth, and on Sept 9 he was readmitted to Mount Vernon Hospital with generalised tetanus convulsions He had continuous trismus and frequent series of opisthotonic spasms, although if undisturbed he would sleep fretfully for periods of 10 minutes without spasm After about 5 hours observation in this state he was given 15 mg (approximately 1 mg per kg body-weight) chlorpromazine intravenously, and within 10 minutes had fallen into a sound sleep with his mouth relaxed for the first time for 3 days 30 minutes later his wet sheets were changed without provoking a spasm, and only one severe spasm occurred in the next 3 hours It was decided to continue with chlorpromazine alone and to increase the dose if necessary An intravenous drip was maintained, and into this, every 2–5 hours, doses of chlorpromazine were given according to the severity of the convulsions

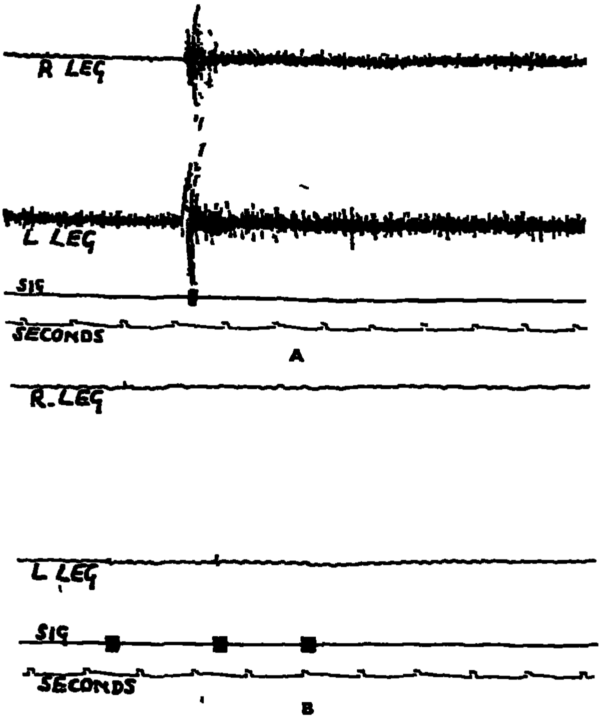

Fig 1—Electromyographs from gastrocnemius region of each hindleg of rabbit after injection of tetanus toxin into left gastrocnemius A severe resting tetanus on left and minimal tetanus on right, with subsequent gross tetanus in both legs, after application of standard afferent stimulus at signal, B, after chlorpromazine 1 *mg* per kg intravenously there is no resting tetanus and three standard afferent stimuli have no effect.

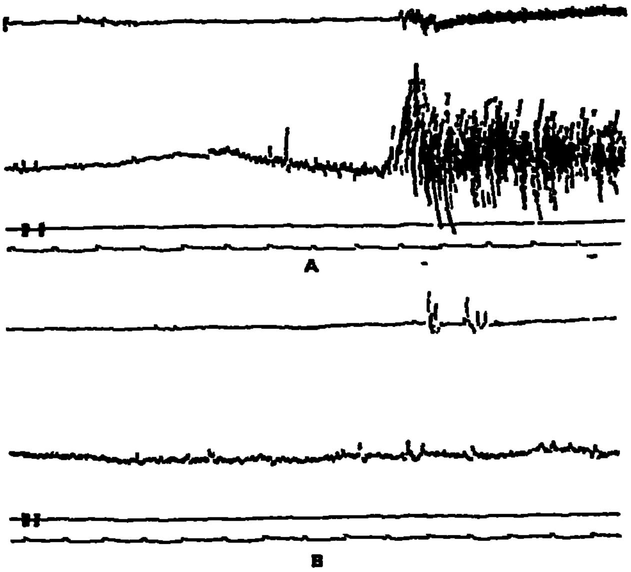

Fig 2—Electromyographs from case of tetanus (surface electrodes) Tracings from above down represent electrical activity of anterior tibial muscles, electrical activity of calf muscles signal, seconds. A, at the signal an oxygen tube was passed up the nose resulting in vigorous spasm of both groups of muscles B, after chlorpromazine the same manœuvre produced no response

The records are not accurately quantitative There is considerable electrode artefact in all tracings, as care was taken to disturb the patient as little as possible in placing the electrodes

The aim was to control the convulsions at a level at which they did not exhaust the child unduly, rather than to achieve complete relaxation (fig 2) That chlorpromazine was effective against the convulsions was demonstrated by their regular cessation or mitigation 20–30 minutes after a dose and their regular recrudescence some time later On three occasions the tetanus became completely out of control, and prolonged and almost continuous severe spasms occurred for 4–6 hours On each occasion it was suspected that the intravenous infusion was not flowing freely, the limb having become grossly œdematous, and on each occasion control was rapidly re-established by an injection of chlorpromazine directly into a fresh vein It was noticed that these occasions each followed a reduction of dosage during the previous night and that a larger dose was required to re-establish control than was needed to maintain control once this was achieved The maximum single dose of chlorpromazine was 40 mg These three occasions also coincided with some extra stimulation—e g, a lawnmower working outside the window, or extensive mouth toilet Apart from these occasions the degree of control varied, but opisthotonic spasms occurred no more than three or four times in a day and minor spasms lasting less than 15 seconds ten to fifteen times a day These spasms usually occurred at nursing times when vigorous afferent stimuli were unavoidable, or 2–4 hours after a dose of chlorpromazine More than half the nursing care, which was applied 30 minutes after a dose, was carried out without provoking severe spasms

At no time was consciousness lost as a result of administering the drug The child was always easily rousable from sleep Respiration was unaffected Phenobarbitone was given to control restlessness as the chlorpromazine was withdrawn Chlorpromazine was given for 16 days, the total daily dose

6 of the patients with cirrhosis showing low spontaneous fibrinolytic activity (cases 24 and 26–30) were each given 1 ml of 1/1000 adrenaline hydrochloride subcutaneously The fibrinolytic activity of the plasma from specimens of blood obtained ten, twenty, forty, sixty, ninety, and a hundred and twenty minutes after the injection was estimated In all 6 cases the fibrinolytic activity was intensified, reaching its maximum within twenty minutes The findings at this time are set out in table III In case 26 multiple petechiæ developed in the skin during the test

Fig 2 contrasts the average findings twenty minutes after the injection of adrenaline in these 6 cases with those in 6 healthy controls From this figure it will be seen that, even when the existence of spontaneous fibrinolysis is allowed for, the response of the patients with cirrhosis was significantly greater The duration of this action of adrenaline was much longer in the patients with cirrhosis than in the healthy controls Fig 3 contrasts the duration of effect in the control showing the most active fibrinolytic response to adrenaline with that of case 26, which is representative of the cirrhotic group

TABLE III—EFFECT OF SUBCUTANEOUS 1/1000 ADRENALINE HYDROCHLORIDE ON FIBRINOLYTIC ACTIVITY OF PLASMA IN 6 CASES OF CIRRHOSIS OF LIVER WITH LIMITED SPONTANEOUS FIBRINOLYTIC ACTIVITY

Cases 2 and 17 were given daily for five days 10 mg of corticotrophin by slow intravenous drip The results are set out in table IV It will be seen that in both cases there was significant reduction in fibrinolytic activity by the fifth day Six days later it had returned to its previous level Case 31 (see table IV) was first seen on the seventh day of treatment with corticotrophin 120 mg intramuscularly daily, when portal-vein thrombosis had developed The fibrinolytic activity of the plasma was negligible, but four weeks later fibrinolysis was complete in less than six hours

Discussion

No influence on fibrinogen was observed in the plasmas showing spontaneous fibrinolytic activity or when this latter was increased by adrenaline or during operation One of us (H C K) has made further observations which show that the fibrinolysin does not act on prothrombin, gelatin, or casein and is unaffected by the serum inhibitor of plasmin It must be concluded that the fibrinolysin found in cirrhosis of the liver is not plasmin It is present in the plasma in active form and is apparently similar to the cadaveric fibrinolysin described by Mole (1948)

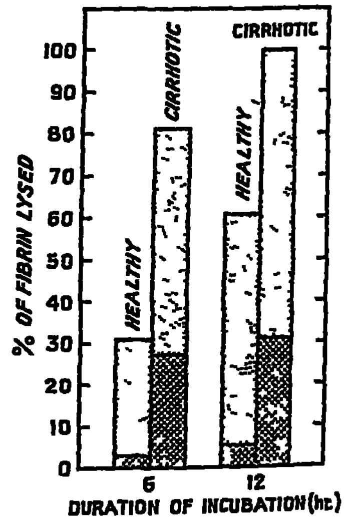

Fig 2—Mean fibrinolytic activity of plasma before and after subcutaneous injection of 1 ml of 1/1000 solution of adrenaline hydrochloride in 6 cases of cirrhosis of liver and in 6 healthy controls *hatched*, before adrenaline *stippled*, increase after adrenaline

Ratnoff (1949), who studied fibrinolysis in 28 cases of cirrhosis of the liver, reported that in 11 of them clotted plasma was lysed within twenty-four hours, and in 15 of the remaining 17 cases between twenty four and forty-eight hours Marrazza et al (1954) found that 5 of 23 cases of cirrhosis of the liver showed complete lysis in twenty-four hours, 15 in forty-eight hours, and the remaining 3 in seventy two hours Both Ratnoff (1949) and Marrazza et al (1954) used recalcified whole plasma, but, as shown by Macfarlane (1937), diluted plasma (used in the present cases) is more sensitive Therefore no comparison of the intensity of activity can be made between these three series It should be noted, however, that our experience is that the fibrin formed by the addition of thrombin is more resistant to fibrinolysis than is that formed by recalcification of citrated plasma

Marrazza et al (1954) concluded that there was a direct relationship between the intensity of the fibrinolytic activity and the severity of the liver lesion Ratnoff (1949) followed the clot lysis time in 6 of his patients as they improved In 2 of these, clinically milder cases than the others, the clot lysis time lengthened, but in the remaining 4 clinical improvement was unaccompanied by any change in the clot lysis time In the present series no relationship existed between the severity of the disease as adjudged clinically, by liver-

Summary

Chlorpromazine and promethazine abolish the muscle spasm of experimental tetanus in rabbits

These drugs probably act by depressing spinal cord interneurones or brain-stem reticular formation

Severe tetanus convulsions in a child were controlled by means of large doses of chlorpromazine alone

We thank Mr R L G Dawson, of the plastic surgery unit, Mount Vernon Hospital, for the opportunity to treat the case reported here One of us (D R L) is grateful to Prof G Payling Wright for helpful discussions The tetanus toxin was given by the Wellcome Research Laboratories We are grateful to the resident medical and the nursing staff of Mount Vernon Hospital, especially Sister K H Joiner, for their coöperation

ADDENDUM

Since this paper was completed Cole and Robertson (1955) have confirmed the effect of chlorpromazine in clinical tetanus when combined with phenobarbitone or chloral hydrate

GENERAL HOSPITAL, BIRMINGHAM

The great value of certain organic compounds of mercury in the treatment of œdema, especially that of heart-failure, is well established and many preparations are now in everyday use The occasional occurrence of side effects, some of them serious, is generally recognised and in particular their effect in causing or aggravating kidney damage Conditions listed in *The Extra Pharmacopœia* (*Martindale*) (1952) as contra-indications to mercurial diuretics are acute nephritis and severe renal damage

Toxic Reactions

We have classified the toxic reactions to these drugs into five main groups

(1) Inflammation at the site of injection.

(2) Reactions attributable to the diuresis These are related to disturbance of electrolyte balance, chiefly chloride depletion and dehydration Pre existing renal impairment predisposes to these upsets. Diuresis may cause concentration of nitrogenous waste products and uremia (Barker 1937) Other manifestations are weakness, muscle cramps, and mental changes, with confusion, restlessness, excitement, coma, and death Acute retention of urine may develop

(3) Reactions caused by the mercury in the drug The most important are renal damage, principally tubular, and gastro intestinal lesions The effects are albuminuria, hæmaturia, the passage of casts, anuria, stomatitis, excessive salivation, and hæmorrhagic colitis A variety of skin lesions have also been described.

(4) Cardio-toxic effects, which include ventricular fibrillation and ventricular asystole Although these are usually ascribed to the mercury ion, animal experiments suggest that different organic preparations of mercury produce different cardiac upsets (Chapman and Shaffer 1947) Further, these effects on the heart have been observed most commonly in animals given large doses *Some of the rare sudden deaths* after intravenous injection of a mercurial in heart-failure in humans are attributed to an effect on the myocardium (Volini et al 1945)

(5) Other sudden deaths after intravenous injection have been regarded as anaphylactoid reactions Other allergic reactions described include fever, erythematous and urticarial skin lesions, bronchial spasm, and pulmonary œdema

Acute attacks of gout, toxic psychosis, digitalis poisoning, spontaneous tetany, cerebral thrombosis, and the precipitation of grand mal in known epileptics have been listed among the toxic reactions Of these, acute gout has been regarded as allergic, the others have been thought to be related to electrolyte disturbances or to dehydration after a large diuresis Marrow depression with neutropenia *and* agranulocytosis has been described

In 1942 Degraff and Nadler reported that all deaths from mercurial diuretics up to that time were associated with intravenous injection We have now traced 3 deaths after administration by other routes 1 followed an intraperitoneal injection (Molnar 1935), another was due to tubular necrosis with renal failure after prolonged dosage, mostly intramuscular (Waife and Pratt 1946), and in the 3rd case severe allergy developed after intramuscular injection (Wallner and Herman 1950)

Mercaptomerin

The need for a safe and effective mercurial diuretic that is easily administered is one which manufacturing chemists have endeavoured to satisfy In mercaptomerin sodium ('Thiomerin' Sodium) a relatively recently introduced organic mercurial, *the makers claims of low* toxicity, satisfactory and often prolonged diuresis (Batterman et al 1949, Herrmann et al 1949, Wmik and Benedict 1949, Stewart et al 1950), and little or no locally irritant effects when given subcutaneously would appear well founded if one excepts some of the earlier batches of drug

The studies of Lehman (1947) in experimental animals suggest that mercaptomerin is very much less toxic than certain theophyllinated mercurials as judged by changes in the Q R S of the electrocardiogram Herrmann and his associates (1949), who noted the effect on the E C G.s of patients treated with intravenous mercaptomerin reported no significant changes in conduction or rhythm The results of intradermal testing in humans (Ruskin et al 1950), of subcutaneous and intramuscular injections in mice (Lehman et al 1949), and prolonged use subcutaneously in routine clinical practice show so little evidence of reaction at the injection site that the preparation has been hailed as the mercurial diuretic of choice for home use by the patient or his relatives (Billman et al 1950, Engelberg and Simmons 1950) These claims have not been accepted universally

Observations on dogs made by Handley and his colleagues (1949) using the intravenous route suggest that, weight for weight in terms of mercurial content mercaptomerin is more toxic than meralluride ('Mercuhydrin') After injection mercaptomerin appears to dissociate somewhat slowly and both the therapeutic effect and infrequency of toxic reactions are believed to be related to that *slow dissociation.* Diuresis is less brisk but more prolonged *than with other mercurial* diuretics Lehman et al (1949) suggest that if sufficient time *for dissociation of the compound* is allowed mercaptomerin develops toxicity similar to that of other organic mercurials

Our purpose is to draw attention to reactions which occurred in 4 patients who received mercaptomerin by subcutaneous injection In 1 the development of hæmorrhagic colitis was ascribed to metallic mercury, while in 3 the reactions appear to have been allergic

Case-records

Case I —Mrs G D, aged 70, was admitted to hospital on Nov 12, 1952, because of increasing exertional dyspnœa for

Ratnoff (1949) found that the clot lysis time was three days or longer in 13 patients with infective hepatitis, 2 of whom were in hepatic coma, and in 6 patients with obstructive jaundice. By the same technique in 28 of 29 cases of cirrhosis he found that it was two days or less. The relative inactivity of the plasma in infective hepatitis has been confirmed by Marrazza et al. (1954).

The relative inactivity of the plasma in primary carcinoma is of interest, as are also the high levels of fibrinogen observed. Since each of the livers was cirrhotic, it seems reasonable to suggest that the development of the carcinoma had led to the disappearance of fibrinolytic activity from the plasma. Although the series is too small to warrant inclusion, evidence is accumulating which indicates that spontaneous fibrinolysis is inhibited in cirrhotic patients during intercurrent pyrexial illness and after gastro-intestinal bleeding.

Summary

A study of the fibrinolytic activity in the plasma of 30 cases of cirrhosis of the liver by the quantitative technique described by Biggs and MacFarlane (1953) is reported.

Fibrinolysis was complete in less than six hours in 7 cases, between six and twelve hours in 9, and between twelve and twenty-four hours in 5. In the remaining 9 cases there was a loss of 25–67% of the initial levels. The average reduction in fibrin content after incubation for twenty-four hours was 83%.

These findings are contrasted with those obtained in 12 cases of primary carcinoma arising in cirrhotic livers and in 20 healthy controls. In the former the average reduction in fibrin after incubation for twenty-four hours was 12%, and in the latter 13%.

No relationship was observed between the severity of the cirrhosis and the intensity of the fibrinolysis.

Splenectomy in 6 patients with cirrhosis caused immediate intensification of the fibrinolytic activity—an influence which passed off within four hours. It is in this period that there is risk of hæmorrhage associated with fibrinolysis. Within twenty-four hours of operation spontaneous fibrinolytic activity ceased.

The subcutaneous injection of adrenaline in 6 cases of cirrhosis led to increased fibrinolytic activity, which was on the average of greater intensity and of longer duration than that in healthy controls.

Corticotrophin administered to 2 of the cases showing active fibrinolysis led to a significant reduction in the fibrinolytic activity on the fifth day. It is concluded that suprarenal cortical activity depresses the spontaneous fibrinolytic activity of the plasma, and may play a part in the development of thrombosis of the portal vein observed postoperatively or during corticotrophin therapy in cirrhosis of the liver. The findings in 1 case of cirrhosis of the liver in which portal-vein thrombosis developed during the administration of corticotrophin are reported. At the time when the thrombosis developed, fibrinolytic activity was absent but a month later it was intense.

The fibrinolysin had no influence on fibrinogen, and it is concluded that it is not plasmin but is similar to cadaveric fibrinolysin described by Mole (1948).

Preliminary Communication

THE INHIBITION OF CLOT LYSIS BY CORTICOTROPHIN

In the course of observations on spontaneous fibrinolytic activity of the plasma in cirrhosis of the liver Kwaan et al.[1] have found that this activity ceased within twenty-four hours after splenectomy and remained absent for seven to twenty-one days before returning to pre-operative levels. They consider that suprarenal cortical activity in the countershock phase may be responsible for the disappearance of fibrinolytic activity and may play a part in the development of postoperative portal-vein thrombosis.

Eisenmenger et al.[2] reported 3 cases of cirrhosis of the liver in which portal-vein thrombosis developed during treatment with corticotrophin. Kwaan et al. observed one patient with cirrhosis of the liver who was first seen on the seventh day of treatment with intramuscular corticotrophin 120 mg. daily, when portal-vein thrombosis had developed. The fibrinolytic activity of the plasma was then negligible, but four weeks later it was intense. Kwaan et al. also reported a significant reduction in spontaneous fibrinolytic activity in 2 cases of cirrhosis of the liver on the fifth day of administration of corticotrophin.

These facts led us to investigate the influence of stimulation of the suprarenal cortex on the lysis of clots produced experimentally.

Methods

In each of 40 adult rabbits thrombosis of the marginal vein of one ear was produced by a minor modification of the technique reported by Grossi et al.[3] A length of the vein was isolated between two bulldog clamps and the medial tributaries occluded by a clamp applied parallel to the marginal vein. A 25-gauge needle was inserted, the vein emptied of blood, and 0·05 ml. of a solution of thrombin 500 units per ml. injected. The vein was allowed to fill by releasing the upper clamp, which was then reapplied. In all the rabbits a firm clot formed, and after fifteen minutes the clamps were removed.

For two days before production of the thrombosis and throughout the period of observation 26 of the rabbits were given intramuscular corticotrophin 10 units per kg. of body-weight daily, divided into 3 doses. The remaining 14 rabbits served as controls. The segments of the veins were examined at short intervals by transillumination and the lengths of clots measured. At the conclusion of the observations all were subjected to microscopy.

Result

In each of the control rabbits the clot disappeared and free flow through the vein was established in from twelve to thirty-nine hours (average twenty hours). Before it disappeared the clot became progressively shorter and free in the vein; thereafter it rapidly disappeared. A biopsy specimen of the vein was taken forty-eight hours after the production of thrombosis, and on histological examination there was no evidence of thrombus. In every case the vein appeared normal.

In 25 of the 26 rabbits treated with corticotrophin the thrombi persisted until the experiment was terminated by the removal of thrombosed segments for histological examination, which in 12 of them was carried out on the sixth day, and in the remaining 13 on the eighth day, after the production of thrombosis. In the exception, forty-eight hours after production the clot had shortened of the fifth and last injection a bloody diarrhœa began and persisted for four weeks, gradually abating No infective cause could be found Sigmoidoscopy on two occasions revealed a granular bleeding rectal mucosa with a few shallow ulcers The urine was normal throughout He was not given dimercaprol (BAL) or other specific treatment for heavy metal poisoning At the time of his discharge on Jan 25, 1954, he was free from all bowel symptoms

Discussion

The reactions in these 4 patients were of two types in the first 3 they appear to have been allergic, while in case 4 the hæmorrhagic colitis is most easily explained by excretion of metallic mercury through the wall of the gut —a well-recognised sequel of poisoning with inorganic mercury. The discussion which follows deals mainly with the allergic reactions

Most published reports on mercaptomerin and the makers' original claims suggest not only a low incidence of reactions at the site of injection but also virtual absence of general systemic toxic reactions Herrmann et al (1949), however, reported 2 patients who had mild systemic reactions—chills, fever, and diarrhœa Gold et al (1952) also reported mild systemic reactions (muscle pain and fever) The systemic toxic reaction was severe in 3 of our patients and mild in 1 (case 3) In cases 1 and 2 the reactions were characterised by severe prostration and circulatory collapse, and in cases 1 and 3 by fever We can find no published account of so severe a reaction as those observed in cases 1 and 2 though reactions more or less similar both in type and severity have been reported with other organic mercurial diuretics given by various routes—e g, Snell and Rowntree (1928) (intravenous 'Merbaphen'), Gelfand (1949) and Harris (1953) (intramuscular mercuhydrin), and Andrews (1931) (*intravenous* 'Salyrgan')

In their time relationship to the giving of the injection and in the prominence of cyanosis and circulatory collapse, the reactions in our patients are very similar to those described following the use of other mercurials Certain characteristics of these reactions suggest an allergic mechanism Harris (1953) points out that they rarely follow the initial dose of the drug Their severity increases with each successive dose and is unrelated to the size of the dose The arguments in favour of an allergic basis are well stated by Gelfand (1949) who, in a patient treated with mercuhydrin, also demonstrated skin sensitivity to serum from another patient treated with mercuhydrin It appears that the effect of the first few doses is to sensitise the patient and that later doses induce an allergic response In most cases and initially this response is mild, fever, chills, and cutaneous eruptions being common manifestations The early reactions in our first 3 patients were of this order When, in such cases, the use of the same mercurial is continued, even in small doses, violent and dangerous reactions may follow (cases 1 and 2) In case 3 if treatment had been continued more severe reactions would probably have occurred Here it may be mentioned that cases 1 and 2 were under the care of different members of the staff and that their assessments of the illness which followed the use of the drug were almost identical In each case those concerned suspected an acute coronary attack and anticipated a fatal result

In case 1 the reaction after the last injection was unusually long and severe Improvement appeared to follow cortisone and we should use that drug again in similar circumstances In seeking safeguards against such reactions, the absence of any past history or family history of allergy in our patients is important Harris (1953) states that preliminary skin-testing is rarely helpful in detecting latent allergy

It is interesting that hypersensitivity to one organic mercurial may not imply hypersensitivity to other members of the group (Fox et al 1942) Conversely, lack of allergic response to one compound is no guarantee that other compounds would be safe (case 2)

The variations in the organic moiety from preparation to preparation could reasonably explain variations in the incidence of allergic reactions Gold et al (1952), who endorse the view that some patients have apparently allergic reactions to mercaptomerin, suggest that dissociation of the organic mercurial into its inorganic and organic moieties is necessary for both the therapeutic action and toxic effect

Our 4 cases were collected within a period of two years from a hospital with about 120 general medical beds and this suggests that systemic reactions to mercaptomerin may not be rare The drug was given as directed by the makers The 4 cases were under treatment when different consignments of drug were in use in the hospital Other patients treated with the same batches of mercaptomerin were not affected

It is apparent that mercaptomerin can cause a generalised systemic reaction Degraff and Nadler (1942), referring to all organic mercurial diuretics, asserted "that all of the commercially available drugs of this group have at some time or another been reported as producing alarming symptoms" Mercaptomerin does not appear to be the exception and reactions to that drug may be extremely severe The patient's history is unlikely to indicate a probable reaction On the other hand, unexplained fever, especially if repeated, after the injection of an organic mercurial is, in our opinion, an indication to stop giving that preparation and to use a different one Attempts to establish the guilt of the original compound are not without risk to life *

Summary

4 patients had systemic toxic reactions to subcutaneous injections of mercaptomerin ('Thiomerin') The reactions did not appear to differ from those induced by other organic mercurial diuretics given by other routes The mechanism of the reactions is discussed

We are grateful to Dr C G Parsons for permission to *publish cases 2, 3, and 4, to Mr J G Williamson for the* diagrams and to Miss J Buckingham for secretarial help

* In the leaflet enclosed with each bottle the makers of 'Thiomerin' Sodium now include the following *note* "Discontinue injections if symptoms of hypersensitivity to mercury appear, as flushing of the face, fever, chills, gastrointestinal disturbances, cutaneous eruptions, pruritus or urticaria Some individuals may be sensitive to one mercurial yet tolerate another"

such deaths should be ascribed to gross mismanagement of anæsthesia He was disappointed that no mention had been made of any therapeutic measure He wondered whether after an anoxic incident ensuing cerebral œdema prolonged and increased the damage, and might hypothermia be indicated to mitigate the damage in this immediate postanoxic period?

Dr B G B LUCAS thought that more stress should be laid on the difference between cerebral anoxia and cerebral ischæmia In the latter not only was the oxygen cut off but in addition there was deprivation of substrate, in these cases the damage was more severe and recovery less likely He had found it difficult to obtain experimental evidence of cerebral damage due to anoxia alone, but ischæmic changes induced by centrifugation were easily demonstrable

Dr F FONSECA (Portugal) asked whether glutamic acid had been tried in cases of cerebral anoxia, and Dr LUCAS replied that he had had no success with it but thought that succinic acid had helped in 2 out of 3 cases of carbon-monoxide poisoning in which he had tried it

Dr D H P COLE drew attention to hyperpyrexia as an important clinical sign He said that he and Dr D E Argent had been treating cerebral anoxia by a dehydration regimen in accordance with the hypothesis put forward by Seldon that some of the cells were reversibly damaged by the anoxia, and that their survival was threatened by ensuing cerebral œdema caused by simultaneous anoxic damage to the cerebral capillaries He had seen beneficial results in cases of cerebral anoxia treated by intravenous 50% sucrose followed by a 10% dextran drip A lot of the terrible post-anoxic sequelæ might be avoided if this therapy were used more often

Dr WOOLF replied that in his view cerebral œdema had only a very small effect on the vitality of nerve cells but was, nevertheless, important as a cause of cerebral damage owing to its effect on nerve fibres and especially myelin sheaths

Professor MEYER, replying to the discussion, said that from the pathogenic point of view anoxia was a combination of direct action of oxygen want on the nerve cells, capillary stasis resulting in ischæmia, and increased permeability resulting in œdema All these factors must be considered in explaining the localisation of the lesions He cited a report by Landenberg that cerebral œdema might exercise particular pressure on certain arteries at the base of the brain or in the depth of sulci

Dr BEDFORD did not subscribe to the use of hypothermia in these cases, he found it difficult to envisage cerebral ischæmia occurring clinically without cerebral anoxia

Dr ALLISON said that the term "organic neurasthenia" was undesirable as it conveyed the impression of a functional origin He had been impressed by the clinical similarity between post-anoxic and some post-traumatic conditions and wondered whether œdema was perhaps a common factor

New Inventions

AN IMPROVED METABOLIC BED

FOR quantitative analysis in the diagnosis and management of disease, accurate collection of urine and fæces over timed periods is commonly necessary Some form of metabolic bed must be used for infants or incontinent patients, and prevention of pressure sores may be difficult if collections are prolonged By means of a specially designed foam mattress on a wooden frame, collections have been made without difficulty from children for several consecutive days for detailed metabolic studies, particularly in phenylketonuria

The mattress (fig 1), made of foam-rubber, has a single central hole 6–8 in in diameter (the size depending upon the size of the patient), and a smaller hole 2 in in front of the main one carries the glass or plastic urinal required for collection in boys The mattress is encased in an impermeable rubber sheath to which the foam-rubber is firmly attached throughout This permits sterilisation and also prevents wrinkling of the mattress, which is one of the principal factors in the development of sores Washable rubber flanges protect the inner surfaces of the two holes, and through the larger hole fæcal collections are made without soiling the mattress The entire mattress can be scrubbed and can be sterilised by autoclaving, either with formalin or by steam sterilisation

The mattress is placed on a wooden frame (fig 2) which has a firm plywood base complete except for two holes corresponding to those in the mattress itself The under-part of the frame is hollow and a flap permits siting of receptacles beneath the holes in the mattress for collection of urine and fæces separately The frame and mattress are made to fit inside a standard child's cot The head of the frame can be raised, this eases nursing and prevents the child slipping off the mattress holes The child rests directly on the rubber skin of the mattress with draw-sheets above and below the holes and with the buttocks resting over the larger hole A cruciform binder, with armholes and with buttons down the back, secures the child in the required position and allows considerable freedom of movement of the arms and legs, only the pelvis being held above the mattress hole A second, similar, restrainer applied correctly —i e, with the buttons at the front—prevents the child from falling forward, but still allows freedom of

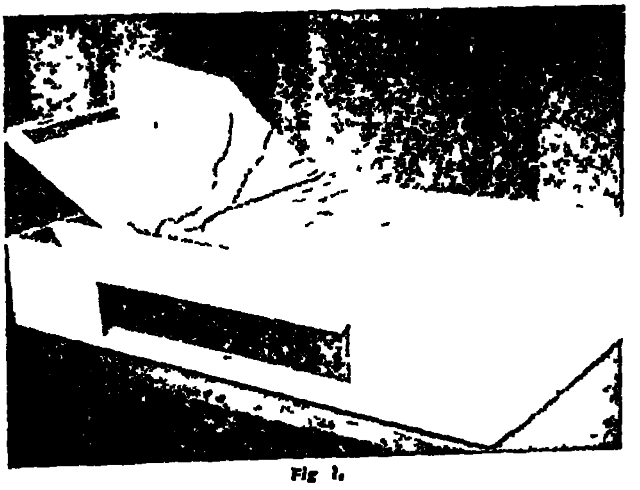

Fig 1.

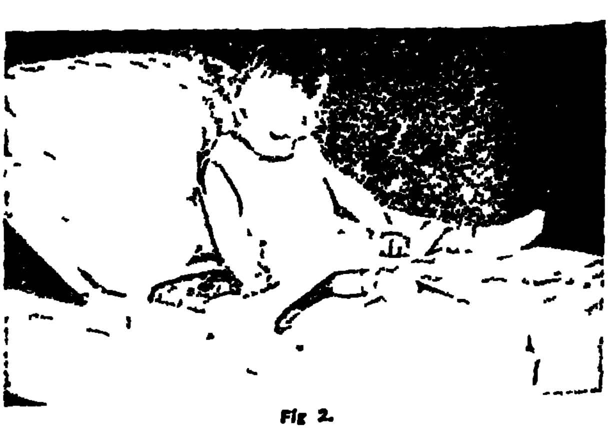

Fig 2.

normal and worked well After some weeks, since the patient seemed so settled, the baby was brought home and the patient looked after him Almost immediately she began to relapse, until she was again so depressed that she had to be admitted to an observation ward. Here once more she made a rapid superficial recovery

She was transferred to the neurosis ward, and was told that she could have the baby in hospital with her, but this she thought was no use since she felt that she would never again be a good wife or an adequate mother She wished to go out to work so as not to be a burden on her family She was allowed to go out to look for a job, but after a time she decided to try having the baby in hospital She became more depressed for a time, and was by now very drawn and haggard Psychotherapy was continued, and gradually the patient did more for the child became less depressed, and made a good recovery which has enabled her to look after her child for the subsequent two years.

Case 3 had been a quiet child, who mixed poorly and had difficulty in asserting herself She was thought to have been spoilt by her parents Her husband was perhaps rather obsessional, but was very reliable and helpful to the patient and was clearly fond of her The baby was wanted; the labour which was normal, was conducted in the patient s own home The patient found feeding the baby difficult, and despite much support and help she became gradually more withdrawn until, when the baby was a month old, she was very strange in manner, and told her husband that she had pneumonia (although really she was physically fit), that she felt that people were accusing her of neglecting the child, and that she was going to be stoned to death She was admitted to the observation ward, where she became well enough to be transferred after seventeen days to the neurosis ward Her husband encouraged her to stay, and brought the baby to her in hospital She was treated by psychotherapy, discussing her fears about the child, and her difficulty in caring for him, besides her past relationships, particularly with her parents She made a good recovery She has remained well and has cared for her child without interruption for two years

Case 4 was brought up in a Dr Barnardo s home from the age of four years, because her mother, who was pregnant at the time of her husband s death could manage to care for only the youngest and oldest of her nine children The mother visited the patient infrequently, so gradually they meant less to each other After leaving the home the patient did a domestic job until her marriage In the puerperium she became depressed, and so was transferred to the psychiatric unit, where she attempted suicide and continued to get more depressed She was transferred to a mental hospital under certificate

After two months in the mental hospital during which she had a course of E C T, she was discharged recovered and was referred back to the outpatient department This patient stayed at home with her husband while the baby remained in the nursery, where he had been while the patient was in hospital The matron of the nursery coöperated with treatment, allowing the patient to choose how much she did for the baby, and encouraging her to come to the nursery as often as she wished The patient attended the outpatient department for psychotherapy several times a week. At this time she discussed her relationship to her husband and child, whereas in her more disturbed state she had discussed her past relationships The patient gradually assumed charge of the baby, until she took him home and was fully responsible for him. She has not relapsed

Six patients have been successfully treated in this way and have not relapsed in the two years over which they have been followed up This series, though small suggests that in cases of postpartum psychosis the patient should be treated in a unit to which her baby is also admitted

This work was done in the psychiatric, maternity, and pædiatric departments of the West Middlesex Hospital.

I would like to thank Dr F P Haldane psychiatrist, West Middlesex Hospital for permission to publish this paper, and Miss H. B Schaler for assisting in the follow up

δ-AMINOLÆVULIC ACID AND PORPHYRIA

A JARRETT
M.B Birm. M.R C P.E
RESEARCH ASSISTANT IN DERMATOLOGY

C RIMINGTON
M.A., Ph.D Camb, D Sc Lond, F R S
PROFESSOR OF CHEMICAL PATHOLOGY IN THE UNIVERSITY OF LONDON

D A WILLOUGHBY
TECHNICIAN IN THE MEDICAL UNIT

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

IN 1954 Goldberg et al showed that porphobilinogen has no pharmacological actions which can explain the symptoms of acute porphyria The immediate precursor of porphobilinogen is δ-aminolævulic acid (Dresel and Falk 1953, Gibson et al 1954 Granick 1954, Schmid and Shemin 1955) which can take the place of glycine and "active" succinate in the synthesis of porphyrin and hæm (Shemin and Russell 1953, Neuberger and Scott 1953) and is excreted in the urine by patients with acute porphyria (Granick and Vanden Schrieck 1955) We have therefore investigated some of the pharmacological properties of δ aminolævulic acid using two samples of the hydrochloride kindly placed at our disposal by Prof A Neuberger, F R S, and Dr J J Scott

During attacks of acute porphyria the patient may have hypertension and tachycardia In the cat, δ aminolævulic acid in doses of 100 μg per kg body-weight (in one test 0 5 mg per kg) did not alter heart-rate or blood-pressure There was neither potentiation nor inhibition of responses to adrenaline or to noradrenaline

Other symptoms of an attack of acute porphyria may be abdominal pain, constipation and distension of the large gut Isolated guineapig ileum gave no response to a dose of 100 μg in a 20 ml bath. In this dosage δ-aminolævulic acid had no effect on contractions produced by histamine, by acetylcholine, and by 5-hydroxytryptamine On isolated rat's colon the same dose had no effect and did not alter the responses produced by acetylcholine and by 5 hydroxytryptamine

The result of this preliminary investigation suggests that δ-aminolævulic acid does not possess any pharmacological properties that might explain the cardiovascular and the abdominal symptoms which are a constant and prominent feature of an attack of acute porphyria δ-Aminolævulic acid administered by mouth to man is rapidly excreted by the kidney (Berlin et al 1954a), as is porphobilinogen (Goldberg and Rimington 1954), and causes no symptoms resembling those of acute

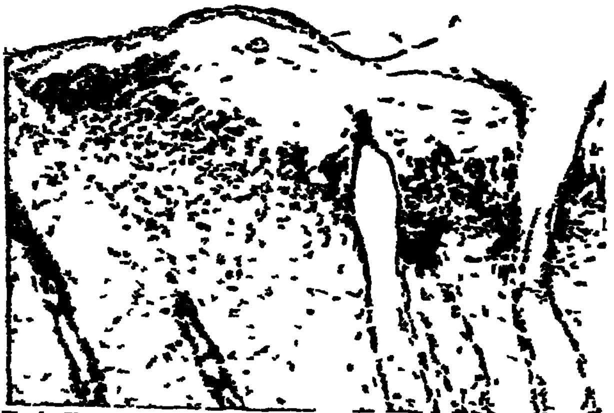

Fig 1—Skin of rat receiving δ-aminolævulic acid and ultraviolet irradiation Note early blister gross damage to collagen, and lymphocytic infiltration (Hæmatoxylin and eosin ×160)

Only the neurological section seems uneven there is, for example, no discussion of the common problem of cervical spondylosis and its effects upon the cord, and the article on acroparesthesia does not mention the good results achieved by decompression of the median nerve

A most valuable feature is the emphasis on the biochemical and physiological aspects of disease, and the account by Professor Loeb of the metabolic processes in diabetes is outstanding

Studies on the Cerebral Cortex

SANTIAGO RAMON Y CAJAL Translated by LISBETH M KRAFT London Lloyd Luke 1955 Pp 179 27*s* 6*d*

DURING 1901 and 1902 Cajal published a series of papers in the *Trabajos del Laboratorio de Investigaciones Biologicas de la Universidad de Madrid*, on the "limbic lobe," which Broca had described in 1878 Cajal's studies were undertaken to discover the relationship of this part of the brain to olfactory function They formed part of a more extensive paper on the origins and terminations of the olfactory, optic, and acoustic nerves in vertebrates which had already been presented to the Royal Academy of Medicine of Madrid Many will be grateful to Dr Kraft for her admirable and careful translation, and to Dr Paul D Maclean who encouraged her to undertake the work and so make another of Cajal's classical studies available to the English-speaking world for the first time in its original form' The publication is timely in view of the present great interest in the control of psychomotor epilepsy The drawings are well reproduced

Selection of Anesthesia

JOHN ADRIANI, M D, director, department of anesthesiology, Charity Hospital, professor of surgery, school of medicine, Tulane University, Louisiana Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1955 Pp 327 47*s* 6*d*

THIS book is best considered in relation to the circumstances of anæsthesia in the United States, where most anæsthetics are still administered by nurse-technicians Supervision may be by an anæsthetist, but is often by the surgeon, so that the selection of drugs and technique may have to be made by someone who has no special knowledge or training in the specialty For him and for physicians who are asked to advise on the fitness of patients for anæsthesia, Dr Adriani has collected a considerable amount of factual knowledge The pharmacological effects of drugs used in anæsthesia, and their relation to non-surgical conditions and to the operation, are set out so that the method best suited to the individual case can be chosen

Some may doubt whether this is the best way of selecting an anæsthetic, since practical experience is often a better guide to safety than a theoretical knowledge of drug action, though a combination of both is obviously ideal Nevertheless, as the doctor must in this case advise the technician, it is as well that he should have some understanding of the problems from the anæsthetic rather than the purely pharmacological or physiological point of view This he can obtain simply and accurately from Dr Adriani's book, but he must make some allowance for the differences in clinical practice on the two sides of the Atlantic

Textbook of Occupational Therapy

With chief reference to Psychological Medicine E N M O'SULLIVAN, M B, D P M, superindentent Killarney Mental Hospital London H K Lewis 1955 Pp 319 21*s*

THIS comprehensive book deals with every aspect of occupational therapy, with special reference to psychiatry It covers the history, objects, organisation, and craft analysis, and there is a description of the mental diseases likely to be met with by the therapists

Dr O Sullivan recognises that occupational therapy covers much more than merely crafts and he sees the importance of recreation pure and simple, as well as work in the utility sections He stresses the importance of constant contact with the doctor who should always prescribe and supervise

The establishment of 3 trained occupational therapists in a hospital of 1000 beds seems very modest, but when the establishment is increased, as Dr O'Sullivan suggests, by attaching nurses and special technicians skilled in certain handicrafts, patients will have the best of different disciplines His re educational scheme is well planned too well planned perhaps, since the complete regimentation that he describes on pp 115–118 might fail to be therapeutic

In contrast to most mental hospitals in this country, the segregation of the sexes in Dr O'Sullivan's hospital appears to be rigid, and apart from entertainments a special occupational therapist is allocated to each sex

This book is a valuable addition to the medical and nursing libraries of the mental hospital

Atlas de chirurgie thyroidienne

JACQUES FRANCILLON, chirurgien des Hôpitaux de Lyon, CLAUDE GABRIELLE, Interne des Hôpitaux de Lyon Paris Expansion Scientifique Française 1955 Pp 180 Fr 3000

BY means of copious and clear illustrations with an explanatory text opposite each, the authors deal fully with the surgery of the thyroid They describe in detail several operation techniques, emphasising the many difficulties and suggesting methods of surmounting them Unfortunately the choice of techniques is left to the reader, who is given no lead as to which the authors think best

Different methods of incision are described, but the writers apparently prefer the old fashioned "U" incision, since this is used in all the illustrations of technique

A chapter is devoted to dislocation of the thyroid, and includes a minute description of its blood supply and all possible methods of hæmostatic control The normal and abnormal anatomy of the recurrent laryngeal nerves and of the parathyroids are fully described

Another chapter reviews the many techniques employed for the resection of the thyroid lobes, with and without exteriorisation And the final chapter describes in minute detail different techniques in suturing and drainage

A wide survey has been made into the literature and techniques of thyroid surgery which should prove extremely interesting to surgeons experienced in this specialty

The Practitioner's Handbook to the Social Services

ALFRED H HAYNES, F W I Bristol John Wright 1955 Pp 124 9*s* 6*d*

WRITTEN by a practising social welfare officer, the book gives a good account of the details of the Welfare State in this country Even those in general practice, who are in daily contact with social as well as medical problems, and who are most familiar with the machinery of the National Health Service, will be surprised at the extent of the social organisation here described The practitioner will find the answers to problems of social administration into which he had some insight but lacked full knowledge

In its fourteen chapters the book includes the work of executive councils, regional hospital boards, and local health authorities, and accounts of National Insurance, National Assistance, Education Housing Legal Aid, and other services to the community Mr Haynes's experience has enabled him to interpret the many Acts of Parliament and other official documents in a readable way

The book will be useful to the visitors to this country who require a short but comprehensive account of our social services, and to the new entrant to general practice

---

Whitaker's Almanack 1956 (London Whitaker Pp 1190 17*s* 6*d*)—This year's issue includes as features additional to its well known repertory (1) the Ministry of Labour's Index of Retail Prices, showing the level for each month from June, 1947, to August, 1955, and detailed figures for the latter month, (2) two tables showing the distribution of gross and net incomes, (3) a table showing personal expenditure and (4) a comparison of the expenditure of Local Authorities and that of the Central Government The principal ships of the Royal Navy at last stage a come back and the national and the local Nature reserves are described the epidermis, suggesting an intensification by irradiation of the transformation into porphyrin Pimenta de Mello (1951) found the urinary coproporphyrin of lead-poisoned rabbits to be much increased by exposure of the animals to ultraviolet rays, and Gillman et al (1945) observed an increased amount of porphyrin in biopsy specimens of human liver from pellagrins after body irradiation

A factor which may play a dominant rôle in determining the distribution of porphyrin after injection of either δ aminolævulic acid or porphobilinogen is the relative ease with which these two precursors may enter cells Fowl erythrocytes permit the ready entry of δ aminolævulic acid but are much less permeable to porphobilinogen (Falk et al 1956) Should these permeability differences extend to other cells, one could imagine the rapid entry into the epidermis (and tissues generally) of δ aminolævulic acid from the body-fluids and its transformation there into uroporphyrin, enhanced perhaps by light, the brilliant fluorescence of the exposed epidermis and its injury under irradiation would therefore be understandable

More detailed work is obviously necessary to substantiate this hypothetical explanation of the present findings, but a further analysis of the problem, together with assays of excreted δ aminolævulic acid and porphobilinogen by patients with porphyria having cutaneous and abdominal symptoms respectively, should help us to understand the chemical-pathological differences between these types At any rate it seems to be acceptable, from the experiments here recorded, that δ aminolævulic acid alone cannot be held directly responsible for the abdominal or cardiovascular disturbances seen in the typical attack of acute porphyria

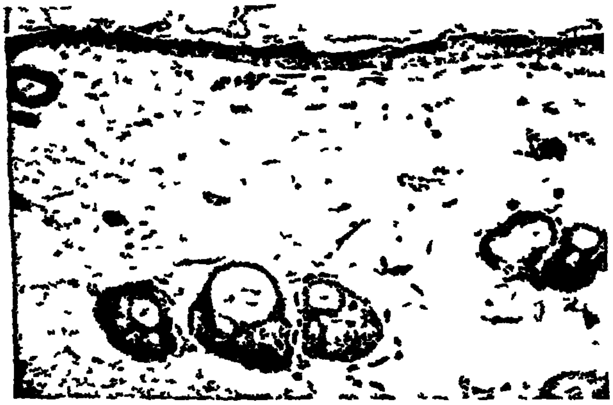

Fig 5—Normal control (Hæmatoxylin and eosin ×160)

Frozen sections were prepared by Mrs J Hardy and photomicrographs by Mr A Bligh Dr R Moulton assisted in the pharmacological preparations, and Miss B Tooth with the urine analyses

A H JAMES
D M Oxfd, M R C P
SENIOR LECTURER IN MEDICINE, WELSH NATIONAL SCHOOL OF MEDICINE

HAROLD SCARBOROUGH
M B, Ph D Edin, F R C P E
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF WALES

From the Medical Unit, Cardiff Royal Infirmary

WE describe here a patient in whom an excessive loss of potassium in the urine was associated with the presence of a benign adrenocortical tumour, and was abolished by its removal When this patient first came under our care, Conn's (1955a) account of primary aldosteronism had not been published, and we were content to attribute the loss of potassium to a primary renal lesion The patient was not acidotic, however, and her urine could be acidified, so her case was comparable to that of Earle et al (1951), and contrasted with the more usual "potassium-losing nephritis" in which failure of hydrogen ion excretion accompanies the inability to conserve potassium

When Conn (1955a) described his patient in whom a salt-retaining hormone was secreted in excessive amounts by an adrenocortical tumour, and suggested that other cases of supposed potassium-losing nephritis had a similar cause (Conn 1954), we reinvestigated our patient (who had meanwhile been kept well with a supplement of potassium) and found a tumour of the right adrenal gland This patient differs from the small number already recorded (Conn 1955b) in several respects, among which was her severe hypertension The satisfactory fall in blood-pressure which followed operation supports Conn's suggestion that other such cases should be sought among hypertensives

Case-report

A housewife, aged 43, was admitted to hospital in February, 1954, because of weakness of the limbs and neck and diarrhœa For nine days she had had up to six watery motions daily, without mucus or blood At 2 A M on the sixth day she was awakened by nausea, on trying to get up to vomit she found that she could not move her limbs or raise her head off the pillow For about three years she had had attacks, each lasting about a week, in which her arms felt stiff and useless, she was unable to perform actions requiring sustained muscular contraction, such as holding a knife to cut bread Her husband noticed that during these attacks her head would loll forward, and that when she walked her feet would slap on the floor About the time that these attacks began she noticed excessive thirst, worse during the attacks, but present also during the intervals between them This was accompanied by nocturia, at first infrequent but becoming more severe, so that she had regularly had to pass urine three or four times a night She had never noticed any abnormality of the urine, nor had she had any symptoms suggesting a urinary infection No member of her family had had any kind of paralysis

Examination

The weakness was patchy and asymmetrical The patient could not lift her head off the bed, abduct either arm, or extend either elbow, flexion of the left elbow, grip of the right hand, and flexion of the hips and knees were also weak Other movements were strong The tendon reflexes were brisk, and place primarily within the cells, which may help to explain the absence of œdema despite considerable sodium retention. A striking feature in the patient described by Dr **Chalmers** and his colleagues was the degree of hypertension, which fell from 220/140 mm. Hg to 160/90 after removal of the tumour. It remains to be seen how far the renal disturbances are permanent: some are directly attributable to potassium depletion and hence are potentially reversible, others may be related to nephrosclerosis.

---

* Present address Department of Medicine Middlesex Hospital London

In the early stages of aldosteronism the correct diagnosis may be suggested by a combination of hypertension and hypokalæmia, which may be suspected from the electrocardiogram. It is important to determine what rôle, if any, aldosterone has in the genesis of essential hypertension: already it has been claimed that the excretion of the hormone is increased in this disease.[27] A puzzling feature of Conn's syndrome is the absence of œdema. Professor **Mach** and his associates have described a woman with recurring attacks of œdema and sodium retention who excreted increased amounts of aldosterone but did not have hypokalæmia or polyuria.[22] They suggest that the clinical picture may be determined by the amount of aldosterone secreted, since small doses of deoxycortone cause salt and water retention whereas, in dogs, large doses induce a polyuria and hypokalæmia.

Contraception

> "*Control by men and women over the numbers of their children is one of the first conditions of their own and the community's welfare, and in our view mechanical and chemical means of contraception have to be accepted as part of the modern means, however imperfect, by which it can be exercised.*"—Royal Commission on Population.[28]

Contraception now plays an important, and many would say a beneficial, part in our daily lives. Apart from those who object on religious grounds, there are probably few married couples who do not at some time employ it. But it is not true, as many unmarried people assume, that there exists "contraceptive information" which makes it possible to avoid or space pregnancies without difficulty, and without prejudice to coital enjoyment. Contraception by the best available methods, occlusive or spermicidal, is a nuisance and often an anxiety. It can be practised with fair success, so far as avoidance of pregnancy is concerned, by educated people with good sanitary facilities, using it upon premeditated occasions, but for the ill-equipped or unintelligent it is quite inadequate. This view is well restated by Dr G. I. M. **Swyer**[29] in the January issue of *Family Planning*, which celebrates the twenty-fifth anniversary of the Family Planning Association. Reviewing the work on contraceptives now in progress, **Swyer** says that research on less clumsy and more reliable techniques for controlling fertility has had a recent impetus from fears about the world's food-supply; and it is reasonable and right to expect contraception to contribute to the solution of this problem. But the tone of some "neo-Malthusian" comment merits the rebuke directed by **James Parkinson** to **Malthus**, that "if the population exceeded the means of support, the fault lay not in Nature, but in the ability of politicians to discover some latent defect in the laws respecting the division and appropriation of property." A more liberal justification for contraceptive research lies in the part which a simple and reliable method could play in extending human freedom of choice and deepening human relationships. The biologist who gives time to this problem need have no doubt that he is meeting a universal human need and wish.

An ideal contraceptive should, in the words of **Parkes**,[30] "be effective over a known period of time, simple enough to be generally available and easily usable by any people intelligent enough to know the possible consequences of coitus, and whether they do or do not wish to conceive. Ideally, it should involve only occasional dosage by mouth. It should certainly not depend on local action contemporaneous with coitus. It should have no other effects than the prevention of conception"—or, of course, prejudice subsequent fertility when discontinued. In seeking biological means of achieving this, attention has been devoted to two groups of substances: (1) antihyaluronidases, which interfere with the penetration of the ovum by sperms, and (2) two materials which have been regarded as hormone antagonists—namely, extract of gromwell (lithospermum), which appears to antagonise the pituitary gonadotrophins, and *m*-xylohydroquinone. This second substance was identified by **Sanyal**[31] as the ingredient of oil of peas which reduced the fecundity of rats on a pea-meal diet, and it seems to antagonise vitamin E and to inhibit the actions of œstrogen and progesterone on the endometrium. Synthetic *m*-xylohydroquinone has had fairly extensive field trials in India,[32] [33] capsules being administered to women monthly at about the time of ovulation; and it certainly appears to reduce fertility. But recent papers by **Sanyal** and his co-workers provide a striking example of the problems which arise in such work. With contraceptives, though toxicity tests in animals can and must be undertaken, clinical trial on human patients, on a large scale, is the only final means of estimating efficacy and judging untoward effects on health, subsequent fertility, and any pregnancies which may occur in spite of the drug. In these respects *m*-xylohydroquinone satisfied its investigators—on the basis of some blood, urine, and pulse-rate investigations during the experiment, undertaken, it seems, to meet criticism from America that toxicity had not been fully excluded; and in view of the fact that it had been previously given to over 800 private patients without complaint, **Sanyal, Banerjee,** and **Sen**[33] conclude that "all these definitely prove that *m*-xylohydroquinone is not at all toxic to the human system." They now propose to investigate its exact mode of action. As the substance concerned is said to be a hormone antagonist affecting both œstrogen and progesterone, one must hope that their confidence is justified, for the tests so far reported would prove the harmlessness of, say, benzpyrene. In present circumstances women in Asia might well be prepared to accept some degree sample of the present patient (May 5–12) showed an abnormally high aldosterone content as far as can be ascertained with the limited data so far available. The extract from this specimen was also extensively fractionated by partition column chromatography, and no biological activity as detected by the Na K method (Simpson and Tait 1952) was found in any fraction except those expected to contain aldosterone At the levels tested, aldosterone therefore accounted for at least 90% of the biological activity in this extract

[33] Sanyal, S. N., Banerjee, S. C., Sen, J. *Ibid*, p. 31.

The results of the assay of the pooled specimen were not available until after operation, so the information obtained from this line of approach at that time was that an excess of aldosterone was not present in the blood or urine It nevertheless seemed necessary to try to demonstrate an adrenal tumour anatomically

Anatomical study —No adrenal tumour was palpable and plain radiography and intravenous pyelography showed no abnormality except poor concentration of the dye, the kidneys were of normal size After presacral insufflation with oxygen (Dr Bryan Williams) plain radiographs although they showed the renal and splenic outlines clearly, failed to reveal an adrenal tumour, but tomograms showed at the apex of the right adrenal a superimposed shadow, almost perfectly round and about 2 5 cm in diameter (fig 2)

Operation

On June 10 the right adrenal was exposed by Mr D B E Foster A friable yellow tumour of the size and position suggested radiographically was found and removed together with the whole of the right adrenal gland. Renal and muscle biopsies were also taken, *the kidney did not look abnormal*

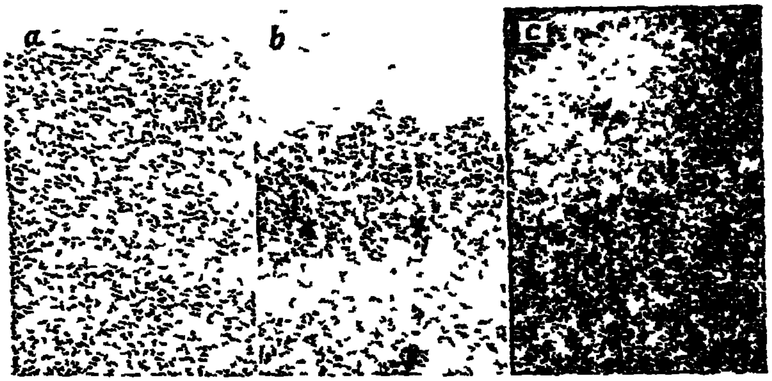

Fig 3—Non-tumorous part of right adrenal gland *a*, hæmatoxylin and eosin *b*, Sudan IV, *c* digitonin with polarised light. Composite photograph showing absence of sudanophilic and birefringent material from zona glomerulosa, and abundant sudanophilic material in zona fasciculata. (×65)

Pathological Reports

Dr H. J Whiteley reported as follows "The *adrenal tumour* was well encapsulated, the cut surface being a uniform golden-yellow Microscopically the tumour was a well differentiated cortical adenoma, showing areas of secretory activity The rest of the adrenal was small, the cortex being 0 4 mm thick (normal 1–1 5 mm) The cells of the zona glomerulosa were small, and contained scanty sudanophilic droplets and no birefringent material. The zona fasciculata was narrow, the cells containing abundant large sudanophilic droplets and some birefringent material. The zona reticularis contained a small amount of sudanophilic material (fig 3) These findings suggest that in the non tumourous portion of the right adrenal (*the left* was not examined) the zona glomerulosa was secreting, and that the zona fasciculata was atrophic and non secreting "

Section of the kidney (Dr A. G Heppleston) showed hypertensive nephrosclerosis with great thickening of the arteries, there was no fibrinoid necrosis Some vacuolation of the tubular epithelium was seen, in order to discover how this vacuolation was distributed in the tubule the biopsy specimen was investigated by the technique of *nephron dissection* by Dr E M Darmady and Miss F Stranack, who reported as *follows* "microdissection of a portion of biopsy material was carried out by the technique previously described (Oliver 1939 Darmady and Stranack 1954) On superficial examination the total number of nephrons appeared to be normal, and interstitial fibrosis was slight or absent On tracing the nephron the outline of the glomerulus was found to be normal (By this technique accurate assessment of the glomerular structure cannot be made) The proximal tubule, however, was abnormal, in that its epithelium was unusually translucent and the tubule was distorted with areas in which the cells were large and vacuolated and the epithelium heaped up (fig 4*a*) When the nephrons were traced lower minimal changes of a similar nature were found in some of the distal tubules, while others, in which the general outline and mucosal pattern were normal showed some increased vacuolation of the epithelium The collecting tubules were normal (fig 4*b*) The striking feature was the localised vacuolation and distortion of the proximal tubule, it is unusual to find changes in the proximal tubule alone without gross lesions lower in the nephron Precise localisation of the lesion may suggest that this is the site of control of acid base balance

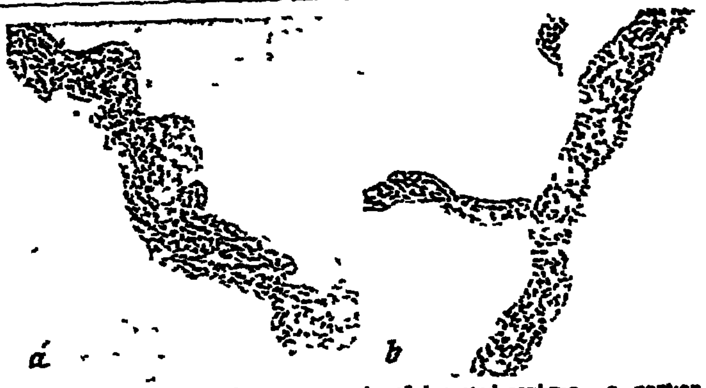

Fig 4—Phase contrast photomicrographs of dissected nephron *a* portion of proximal tubule showing distortion and vacuolation of epithelium (×95), *b*, portion of the distal tubule showing that the outline and arrangement of the tubule is normal some increased vacuolation of the epithelium is seen (×64)

Postoperative Progress

The operation itself was uneventful By the third day after operation moderate lumbar œdema had developed but this subsided over the next few days The only subjective change caused by the operation was the abolition of the thirst and polyuria The average urine volume during eleven days in April, 1955, was 2340 ml per day, and during thirty days after operation 1438 ml (The maximum specific gravity, however, was still only 1 012 ten weeks after operation)

The effect of operation on the *blood pressure* is shown in fig 5, which compares the levels during the admission before operation with those during convalescence During the patient's stay in hospital for investigation her blood pressure tended to fall and the pulsus alternans disappeared, but the blood-pressure two days before operation was 205/130 mm

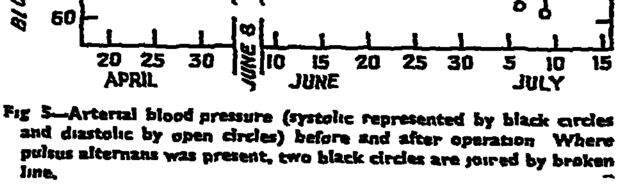

Fig 5—Arterial blood pressure (systolic represented by black circles and diastolic by open circles) before and after operation Where pulsus alternans was present, two black circles are joined by broken line.

broad-spectrum antibiotics in general, or the risk of blood dyscrasia, which is associated with chloramphenicol in particular. Postural drainage, bronchoscopic aspiration of pus, aerosol administration of drugs, and instillation of the appropriate antibiotic directly into the affected segment of lung are adjuvants to chemotherapy which have been advocated,[1 5 9–13] but Shoemaker et al consider them unnecessary. Surgery, they believe, should be confined to resection in cases in which there is recurrence after adequate medical treatment, in which bronchial drainage is impeded by organic obstruction, or in which carcinoma is suspected. These views are now probably widely accepted, although Waterman et al[5] have lately contended that the pendulum has swung too far away from surgery. They think that there is a restricted field in which external drainage is preferable to resection—in old, feeble patients, for example. They believe also that many physicians have an exaggerated idea of the decline in incidence of simple lung abscess, but whatever the exact fall, there seems little doubt that the condition is nowadays much less common in hospital practice than it was, probably because of the alacrity with which chemotherapy is given when there is evidence of respiratory infection. When a lung abscess is encountered it is, therefore, all the more important to bear in mind the possibility of an underlying bronchial carcinoma[8 14] or foreign body, and it is probably wise to carry out bronchoscopy in all cases irrespective of the initial response to treatment.

OBSTRUCTION OF THE SUPERIOR VENA CAVA

THE superior vena cava is most often occluded by external pressure from malignant tumours or aortic aneurysms, and when such lesions are present it is neither reasonable nor possible to try to relieve the obstruction by operation. But sometimes the obstruction may be the result of a more benign process, such as phlebitis, chronic fibrosing mediastinitis, or mediastinal tuberculous lymph-glands. Although many patients with an obstructed superior vena cava have no symptoms, the rise in venous pressure may cause persistent cyanosis, swelling and venous engorgement of the head and neck, and severe headaches and dyspnœa. For these patients operation may be indicated. Replacement of the great veins presents problems different from those of arterial grafting. The venous wall is thinner and more compressible, and the blood flows more slowly and at a low pressure. Consequently any disparity in length or diameter results in angulation or ridging of the graft, and this may lead to thrombosis, particularly at the suture line.

Deterling and Bhonslay[15] have replaced the superior vena cava in dogs by various materials. Aortic homografts, they found, were easy to handle and suture into place, although within a few weeks of insertion the graft shrank to an elliptical cross section with internal furrows and corrugations. They say the functional results were reasonable even though the diameter of the graft was eventually reduced by 40%. Venous autografts worked very well at first, but all of them were completely occluded by thrombosis within a month. Synthetic materials were even more disappointing and none of those tried, including 'Ivalon' sponge, 'Dacron' taffeta fabric, and woven seamless nylon, functioned satisfactorily. In the patient they treated, who had complete caval and azygos obstruction by tuberculous glands, the thrombosed segment was resected and replaced by an aortic homograft. This has worked well for eighteen months and the patient's symptoms have been completely relieved. This is the 9th case so far reported in which a superior-vena-caval obstruction has been treated by grafting. In 6 of these the venous autograft either thrombosed after operation or was described as a "partial" success. After the other 3 operations, in which aortic homografts were used, 1 patient died four months later, at which time the graft was patent, and 1 graft was a failure; the 3rd is the case described by Deterling and Bhonslay. They rightly conclude that this generally unsatisfactory picture underlines the need for further investigation into large vein replacement.

CUTANEOUS LYMPHATICS

THE part played by lymphatics in vascular diseases of the legs continues to interest clinical investigators. Butcher and Hoover[1] have studied the abnormalities of cutaneous lymphatics associated with stasis ulcer, lymphœdema, and cutaneous autografts. Their method was essentially that of Hudack and McMaster[2], sky blue dye (in aqueous 4% solution) was injected through a 30 gauge needle into the most superficial layer of the dermis. The spread of the dye locally can be recorded photographically, and massage and movement of the foot or leg drives the dye proximally to the collecting lymphatics and glands. Butcher and Hoover found that the patterns of superficial dermal lymphatics in the extremities of normal individuals showed little variation in length, diameter, or number of channels and that the pattern was more difficult to demonstrate in thin skin. Similar forms of lymphatic spread were seen in the skin around uncomplicated varicose veins; in the presence of cutaneous pigmentation the lymphatics were dilated and the dye diffused more rapidly through these walls. After a stasis ulcer had developed the lymphatic network in the surrounding skin failed to fill, although Kinmonth[3] demonstrated patent lymphatics in the deep tissues underlying stasis ulcers. It is hard to decide whether the lymphatics are obliterated immediately before the ulcer forms or whether the obliteration follows infection and sclerosis secondary to the ulcer.

Superficial lymphatics were also observed by the dye method in 22 partial-thickness skin-grafts in the leg. The channels in the donor skin persisted in a dilated form for three to six months after the grafting, but with longer intervals the calibre of the lymphatics seemed to return to normal in the skin which remained pliable and normal in texture and colour. In contrast, lymphatic channels could not be identified in the scaly, weeping, and pigmented grafts. Many connections between the lymphatics in the satisfactory grafts and those of the skin around became obvious two to four months after grafting. These findings suggest, according to Butcher and Hoover, that the establishment of lymphatic channels between the donor and host skin is of considerable importance and where this fails successful resurfacing cannot take place. The corollary to this is that excision of an ulcer prior to grafting must be wide enough to include all tissues in which lymphatics have been obliterated.

Lymphatics could not be demonstrated by Butcher and Hoover in the involved skin of patients suffering from lymphœdema præcox—in striking contrast to the findings of Kinmonth and Taylor[4] that a network of abnormally dilated lymphatics could be consistently outlined after intradermal injection of patent blue V. Kinmonth and Taylor exposed the distended channels and injected X-ray contrast media, which displayed the

* Mokotoff et al 1952

relatively slowly at first There was a remarkable coincidence between the calculated increase of intracellular sodium plus potassium and the clinical manifestation of tetany (fig 7) (cf Fourman 1954)

During the postoperative period the balance measurements show an apparent gain, over thirty days, of 260 m eq of sodium, 764 m eq of chloride, and 610 m eq of potassium These figures are surprising in view of the results of isotope dilution (table III), which showed a loss of 707 m eq of sodium The gain of 433 m eq of potassium found by this method agrees well enough with that found by the balance method The postoperative isotope determination coincided with the end of the balance period, but the preoperative determination was made three weeks before operation, so exact concordance is not to be expected A more important probable cause of the discrepancy is the occurrence of unmeasured losses of sodium in sweat during the balance measurement, which was made during unusually hot weather These losses may be large enough to account for the different results obtained by the two techniques Wilson et al (1954) compared the results of balance measurements with those of two isotope measurements In the case of sodium, in all instances where the discrepancies were large the balance method showed the greater gain, discrepancies up to 259 m eq per week were observed, and were attributed to unmeasured extrarenal loss of sodium The daily errors added together for the whole period of thirty days make the cumulative balance figures untrustworthy, but the balance study provides reliable information about electrolyte gains and losses over short periods In particular it shows that there was not a sudden large loss of sodium after removal of the tumour, during the first five days after operation balance showed an apparent gain of 221 m eq of sodium While this gain may have been overestimated because of extrarenal loss, the existence of sodium retention is corroborated by the appearance of œdema at this time

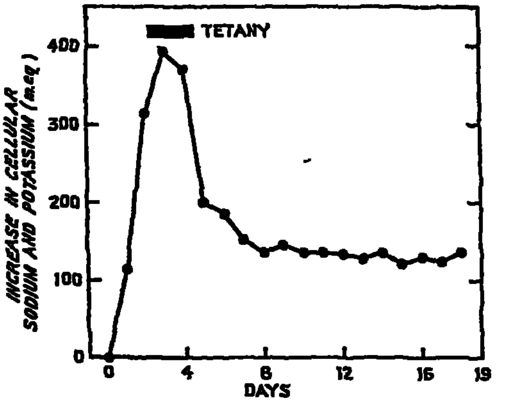

Fig 7—Calculated increase in cellular sodium plus potassium correlated with appearance of tetany

Discussion

Our patient resembles in many respects that of Conn (1955a and b) Both presented with potassium depletion due to excessive renal loss which was abolished by removal of an adrenocortical tumour Both had hypernatræmia, thirst, and polyuria, and these also were abolished Both had hypertension, but this was severe only in our patient In both the salivary sodium/potassium ratio was depressed, and this ratio increased after operation Conn's hypothesis that the syndrome is caused by excessive secretion of salt-retaining hormone was confirmed in his case by the presence of large amounts of this hormone in the urine and in the tumour itself

There are, however, several differences between Conn's patient and ours In the first place it has not been possible to demonstrate more than a small increase in the urinary excretion of aldosterone In the second place, our patient did not lose a large amount of sodium immediately after operation, on the contrary she became œdematous on the third day This difference may be accounted for in several ways Conn's patient received an infusion of hydrocortisone during and just after operation, which may have promoted a sodium diuresis In our patient the potassium supplement was discontinued at the time of operation, and we have demonstrated that this might lead to sodium retention Another possibility is that the fall in blood-pressure, much greater in our patient, might have reduced her glomerular-filtration rate enough to limit her capacity to excrete sodium At all events, in retaining sodium she was responding normally to an operation This response does not seem to depend on any increase in the secretion of adrenocortical hormone (Mason 1955)

We would also like to draw attention to the almost complete absence of alkalosis, in marked contrast to Conn's case Among other cases of proved or presumed primary aldosteronism, one had no alkalosis (Earle et al 1951), while others did (Evans and Milne 1954, Mader and Iseri 1954) Our patient had tetany only during repletion with large amounts of potassium, when there was evidence of an increase in intracellular cation

Before the tumour was removed it was uncertain whether the blood-pressure would fall subsequently. It seemed possible that the hypertension was caused either by renal damage or by a hormone secreted by the tumour On the latter hypothesis, the pressor effect might have been exerted either directly or through the disturbance in body content and distribution of electrolyte The satisfactory fall in blood-pressure which, in the event, followed operation has not enabled a firm choice to be made between these possibilities Removal of the tumour has lowered the output of aldosterone to a subnormal level, and converted a salt plethora at least transiently into a salt depletion, with low serum-sodium level and a low total exchangeable sodium (34 6 m eq per kg) Such changes might lower the blood-pressure in hypertension due to any cause, including renal damage On the other hand the serum-sodium level has since returned to normal, while the blood-pressure remains well below preoperative levels The observed facts would, however, be consistent with the hypothesis that the hypertension was due to a hormone secreted by the tumour

As between the possibilities that the hormone caused hypertension directly, or indirectly through electrolyte disturbance, we can only say that the blood-pressure fell, not immediately after removal of the tumour, but during several days Also, our observations on heat elimination from the hand did not resemble those reported in phæochromocytoma (Hamilton et al 1953), where the hypertension is undoubtedly caused directly by a circulating hormone If the hypertension was caused through electrolyte disturbance the hormone responsible was probably aldosterone itself, since this steroid accounted for 95% of the biological activity in the mineralocorticoid assay While suggesting that aldosterone caused the hypertension by producing a salt plethora, we feel obliged to mention that there is, as yet, *no direct evidence* that this hormone will produce hypertension in the same manner as deoxycortone acetate and other corticoids (Gaunt 1955)

A disturbing consequence of the fall in blood-pressure has been the reduction in renal plasma-flow and glomerular-filtration rate, resulting in nitrogen retention † These reductions, being proportional to the fall in blood-significantly high proportion of young women with secondary amenorrhœa could be classified as obese

---

† Because of the fall in renal clearances after operation interpretation of the urinary steroid values is *difficult*, but compared with the last values obtained before operation urinary excretion of cortisol has been reduced by a factor of 2 5, whereas the corresponding factor for aldosterone is 25

There is no good reason to believe that fertility commonly suffers when a woman gains weight *after* childbirth In a study of parous obese women, Odell and Mengert[13] recorded an average parity of 4 5 (which they thought high) among their patients at the time of interview, and Sheldon[8] found no evidence of menstrual upset (or of infertility) among a group of women complaining of obesity following pregnancy Certainly many women who become very fat after pregnancy have unimpaired fertility, but this is not true for all It is impossible to progress further without recognising different clinical groups of obesity "Simple obesity"[14] is certainly not always simple, although it may not fall into the category of any of the grosser endocrinopathies Sheldon[8] found two distinct groups amongst his patients, one of which appeared to be the pre diabetic group, and there may well be other clinical subgroups If hypothalamic disturbance (which can be of psychogenic origin) causes obesity by promoting excessive appetite, then it is reasonable to suppose that a secondary pituitary upset may cause gonadal failure in these women Thus, it is probable that, with advancing knowledge, more and more cases of "simple obesity" will fall into the category of true endocrinopathies, and Widdowson's views on reproduction and over-nutrition may be confirmed

PLAIN RADIOGRAPHY OF THE INTESTINE

WITHIN twelve hours of the birth of a normal infant air has become dispersed through the entire length of the gut,[15] and thereafter in health it is never entirely absent Some gas is nearly always found in the fundus of the normal stomach, in the colon, and in little collections in the small bowel Because of its low radio-opacity it forms an excellent natural contrast medium In intestinal obstruction, straight radiographs of the abdomen can give valuable information about the site and sometimes the nature of the obstruction The bowel below the level of the obstruction soon becomes empty of gas, while the loops above become distended with gas and fluid In lower ileal obstruction, distended loops of small bowel form a step ladder pattern across the abdomen, and the colon is collapsed and empty of gas When the obstruction lies in the colon, it may be hard to distinguish distended colon from distended small bowel, but generally the lateral position and deep haustra of the colon can be separated from the thinner and more frequent folds of the ileum or the still more feathery pattern of the jejunum The higher the obstruction, the less the radiological signs, especially if vomiting keeps the bowel empty

X ray examination cannot exclude strangulation of the gut, but Frimann-Dahl[16] has pointed out that in a strangulated loop only sanguineous fluid collects, and the loop may be visible as a rounded tumour like mass set amongst gas filled gut Should the volvulus be incomplete, gas can enter the loop and give the "coffee bean" sign of Rigler The gas shadows sometimes serve to show the nature of an obstruction due to internal herniation distended crescentic loops of bowel in the right hand side of the abdomen point to herniation into the lesser sac Gallstone ileus produces the triad of gas in the biliary tree, small-bowel distension and the faintly calcified shadow of a large stone in the terminal ileum In paralytic ileus both large and small gut are dilated, and X ray examination is helpful here in excluding obstruction of the small bowel so that conservative treatment can be pursued with greater confidence The progress of intubation and decompression can then be followed on serial films In peritonitis, exudate may separate the loops of gut and the properitoneal fat lines disappear Localised abscesses—e g, from an appendix—may be outlined by gas filled bowel In ascites the gut floats on top of the fluid when the patient is erect, and the density of the lower abdomen is much increased by large effusion When the gut has perforated, it may take some time for air to percolate upwards and become visible below the diaphragm in films taken with the patient upright, and in all patients a supine lateral film will show gas between liver and anterior abdominal wall

Straight radiography of the abdomen is particularly valuable in children, in whom the gas shadows are often more pronounced In the newborn it may give valuable clues to the malrotations and atresias[17], and the length of the stenosis in imperforated anus can be estimated Signs of small bowel obstruction in an otherwise normal abdomen may point to meconium ileus, and the faint intraperitoneal calcifications of meconium peritonitis may be detected In an "acute abdomen" the cautious administration of lipiodol to a child (or barium to an adult) is not now regarded with the same disquiet as it used to be, and this move will often provide valuable additional information

DEATHS DURING ANÆSTHESIA

THE report of the Ministry of Health for 1954 records[18] that the number of deaths during anæsthesia in England and Wales has declined year by year since 1938 In 1953 there were 562 deaths, 284 of them in men and 278 in women, or about 1 per 1000 of all deaths in the population These figures cannot be accurately related to the total number of anæsthetics given in the same year, for which there are no recorded statistics but in 1954 the Ministry made a pilot survey which showed that about 8 million anæsthetics were administered during that year in the hospitals of England Though the over-all figure for deaths is declining, for patients over the age of 65 there is an upward trend This is perhaps not surprising, particularly in view of the fact that more major operations are being carried out on older people It is, moreover, in accordance with the findings of Beecher and Todd,[19] who recently investigated the mortality due to anæsthesia in ten teaching hospitals in the United States Wisely, no attempt has been made to correlate particular agents or techniques with mortality (indeed, it would not be fair to do so with the data available) but it is interesting to note that thiopentone alone was mentioned on the death certificates in 314 anæsthetic deaths in the period 1949–53

The Ministry's report gives grounds for satisfaction and it reflects how successfully anæsthetists have advanced their specialty in the post war years Nevertheless, some may ask whether these figures really do tell the true story Sudden death due to anæsthesia rarely gives rise to specific post mortem findings, and, as the report points out, the only person who really knows the cause of an anæsthetic death is the anæsthetist who gave the anæsthetic Useful results are likely only from a well planned investigation, such as that organised by the Association of Anæsthetists of Great Britain and Ireland with detailed and first hand accounts of the actual occurrence

Fibrinolytic activity was determined by the quantitative technique described by Biggs and Macfarlane (1953) The initial level of fibrin was taken as that estimated thirty minutes after the addition of thrombin, and the duration of incubation was arbitrarily selected as six, twelve, and twenty-four hours To ascertain whether the fibrinolysin also destroyed fibrinogen, duplicate sets of tubes were set up containing the same quantities of citrated plasma and buffered saline solution, but the thrombin was added after incubation for six, twelve, and twenty four hours, and thirty minutes later the fibrin contents were estimated To determine whether clotting was necessary to activate the fibrinolysin, washed fine fibrin webs, formed on roughened glass rods, were immersed in specimens of undiluted plasma showing active fibrinolysis These webs were formed by adding thrombin to a 1/25 dilution of normal plasma in veronal-acetate buffered saline solution of pH 7 4

Results

The fibrinolytic activity of the plasma in the 30 cases of cirrhosis is set out in table I From this it will be seen that fibrinolysis was complete in 7 cases in less than six hours, in 9 between six and twelve hours, and in 5 between twelve and twenty four hours In the remaining 9 at the end of twenty four hours a variable but reduced quantity of fibrin remained, representing a loss of 24–67% of the initial amount (average 41%) The average reductions in fibrin content in these 30 cases are set out graphically in fig 1 in which they are contrasted with those of 20 healthy controls In the controls the reduction in the fibrin content after incubation for twenty four hours was 0–32% (average 13%)

No relationship could be demonstrated between the intensity of the fibrinolysis and the severity of the disease assessed clinically either by tests of liver function or by the appearances on aspiration biopsy Indeed, cases 26 and 27 with limited fibrinolytic activity were adjudged among the most seriously ill There was no correlation with the presence or absence of ascites or with the plasma albumin and plasma globulin levels All the patients had gross splenomegaly with pancytopenic hypersplenism

* Not done

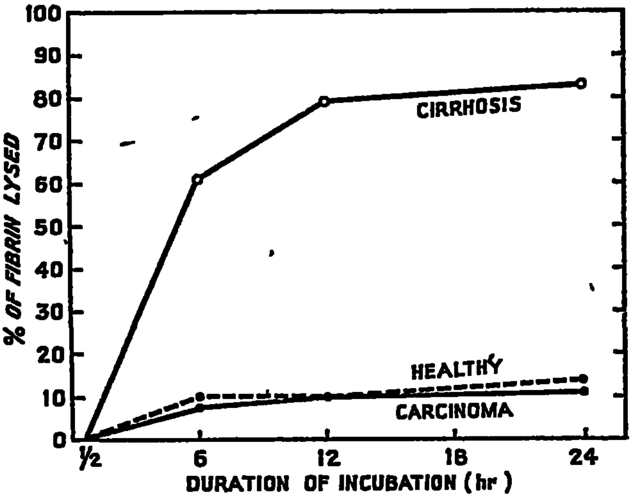

Fig 1—Average fibrinolytic activity of plasma in 30 cases of cirrhosis of liver, 12 cases of primary carcinoma of liver, and 20 healthy controls

The disappearance of ascites with treatment exerted no influence on the intensity of the fibrinolysis, nor did clinical improvement in the patients' condition Repeated observations in 10 cases for from one to three months showed decreased fibrinolytic activity in 3, the clinical condition in 1 had deteriorated, whereas in the remaining 2 there was little change

The incubation, even for twenty four hours, of unclotted plasma from each case did not reduce the fibrinogen content Fine fibrin webs, prepared as described above, lysed when immersed in specimens of undiluted plasma showing active fibrinolysis

The average reductions in fibrin content in the 12 cases of primary carcinoma, each of which arose in a cirrhotic liver, are set out in fig 1 After incubation for twenty-four hours the reduction in fibrin content was 0–30% (average 12%) The initial levels of fibrin were 272–722 mg per 100 ml (average 466 mg per 100 ml)

6 patients with cirrhosis (cases 3, 4, 9, 21, 29, and 30) had undergone splenectomy under general anæsthesia to correct the associated pancytopenia, and fibrinolytic activity was determined at intervals during and after the operation The results are set out in table II Specimens of blood taken fifteen minutes after removal of the spleen in each case showed an intensification of fibrinolytic activity This increase was well marked except in case 29

In case 3 no clot formed on the addition of thrombin to diluted plasma, so the fibrinolytic activity was estimated on undiluted plasma, and lysis was complete in all the tubes when first inspected after thirty minutes In this case whole blood clotted in fifteen minutes but was fluid again within thirty seconds

Cases 3, 21, 29, and 30 were investigated four hours after splenectomy, when the fibrinolytic activity was found to have reverted to the preoperative level in each case

In the 4 patients showing active fibrinolysis preoperatively (cases 3, 4, 9, and 21), the plasma twenty-four hours after splenectomy showed well marked reduction in activity Though not recorded here this reduction was found to persist for seven to twenty one days 3 of these patients (cases 3, 4, and 9) were reinvestigated a month after operation, when the fibrinolysis was found to have returned to its preoperative intensity and biological studies affect their attitude to it , and of giving an exemplary study to its patients in the application of science and logic to an ethical problem Most of my comment here will deal with the committee's views on homosexuality—in part because modern knowledge has added remarkably little to our attitude towards prostitution, and because (judging from the past) no law or recommendation is likely to have any significant effect upon any but the most obviously professional form , but chiefly because it is society's attitude towards homosexuality which calls most urgently for revision today

* * *

It seems to me that a distinguished committee has worked hard, has tried to set a moral and social example, and has made a number of humane and sensible suggestions, and simultaneously, by the language of some passages of its report, has thrown away an opportunity which will not soon recur It has dissipated any chance of serious ethical discussion in a series of pontifications Doctors, the Departmental Committee may conclude, are no different from the rest, though they express their prejudices in longer words This is a disappointing conclusion, even if it might have been expected it is instructive, however, because the striking discrepancy of tone between the scientific and the exhortatory passages of the report suggests that even on an expert committee there has been a distribution of function exactly like that in society as a whole The report reads as a dialogue between a sensible psychiatrist of conservative opinions, and an *alter ego* of a very different kind The scientific have said their say, but the final document gives a strong impression that it has been written in its rhetorical passages by a single person of definite and restrictive opinions

> "At the present time doctors observe their patients in an *environment favourable to sexual indulgence*, and surrounded by irresponsibility, selfishness and a preoccupation with immediate materialistic satisfaction There is also no lack of stimulation to sexual appetite Suggestive advertisements *abound provocative articles appear in the daily*, and especially the Sunday, newspapers "

That paragraph could not, I think, have been the work of a committee, and most of the report's ethical comment bears tokens of the same hand There is a strong suggestion throughout that if deviant sexual behaviour is wicked, its wickedness depends on the same factor which made the Puritans, according to Macaulay, object to bear-baiting the hypothetical writer is one who would never use the word "enjoyment" where he could substitute "indulgence"

The psychiatric members of the committee, who have done their job well, would probably agree that public reaction to homosexuality has a close affinity with the psychology of anti Semitism, and with the pursuit of heretics who menace the tribal magic Such thinking is possibly the result of people's overreaction against components in their own make-up and it could well be argued that the presence of individuals overreacting in this way in the various organs of society, especially Parliament and the courts, is more harmful in the long run than that of conscious and practising exponents of the hated behaviour whose existence the committee has earned notoriety by stressing For homosexuality this stream of disturbed opinion has created a characteristic terminology, based on typically adrenergic words such as 'unnatural vices" "moral fibre" which is sapped, and "unmentionable" practices which are indulged in

Quite the worst feature of the B M A 's evidence is that it has bodily taken over this diction The conspiratorial atmosphere is maintained by repetition of words like "insidious," corruption,' perverted' "indulgence" (We even encounter the expression ' homosexuals and their sympathisers,' which brings to mind the disclaimer in press correspondence denying that the writer is a Communist or a Communist sympathiser Some such equivalent phrase may soon be required in medical articles) The *general tendency* of this diction is to reverse the sense of the scientific evidence, and to counter any emotional disinflation of the subject That a predominantly psychiatric and scientific committee should let itself be reported in such language is frightening

* * *

The committee might, perhaps, properly reply that whatever they had said they would have failed to satisfy all shades of extremist opinion, and that if persons who are neither psychiatrists nor engaged in research on human behaviour feel that the report's recommendations are misguided, they should send their views to the Departmental Committee This is fair enough, perhaps yet a report which is made in the presence of such an opportunity as this, and which welcomes with both hands the chance to combine science and ethics, does invite public comment Moreover it is not the recommendations of the B M A special committee which are disappointing most of them are, as I have said, humane and sensible , and they probably do in fact represent a modal average of medical opinion in this country The disappointing feature of the report is far less its matter than its manner Its failure is almost wholly one of attitude, and much of it lies in the presentation—often the verbal presentation—of what the committee has to say

As a contribution to healing it incurs three charges first, it is couched in language which throws away the fundamental point of difference between the medico scientific approach to unpopular sexual behaviour and that of society, or the Sunday Press Secondly, its discussion of scientific data is skeletal, the bones being apparently chosen to avoid dangerous thoughts, but clothed in a great deal of moral adipose tissue And thirdly, it offers no single comment on either of the two aspects of homosexual conduct which medicine is almost alone qualified to discuss—the reality of the moral and physical ill effects on individuals and society which might justify prohibiting it, and the psychosocial origins of the attitude which society adopts toward it I do not think these are unfair criticisms at least they provide as good a peg as any upon which to hang a discussion of the responsibility of medicine for giving insight to public opinion

Neither is the committee much happier in its encounters with biology, although the scientific sections are gratifyingly written, from the standpoint of diction and attitude, "in another hand" It provides no adequate review of the literature, and the bibliography contains six references, though other work is quoted in the text Its brush with genetic determinism is important, for the 'essential" homosexual real or imaginary is a potentially important intruder in legislation Beside his popularity with predominantly homosexual individuals, who share the general comfort which we derive from "organic" explanations of our peculiarities he could very easily acquire a legal status according immunity to himself and continued punishment to others who cannot prove their activities to be 'essential rather than merely experimental

There is one scientific omission moreover, which cannot be overlooked "Homosexual" behaviour is presumably the display, between individuals of the same sex of an imitation of reproductive mating behaviour, which may or may not end in some kind of sham copulation It occurs under ordinary conditions of observation almost universally among immature and segregated, and not uncommonly in adult unsegregated males of most if not all mammalian species as well as in other bisexual organisms Similar behaviour has been described between human males in every culture of which we have record, without any obvious psychotic

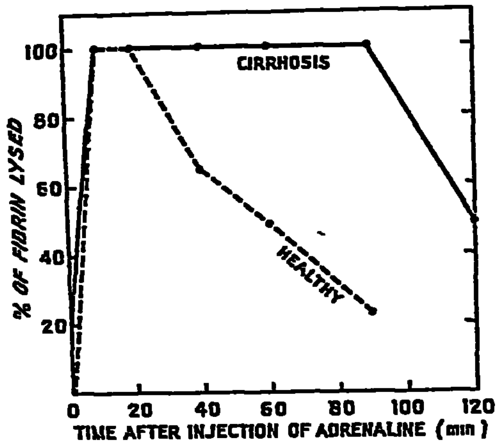

Fig 3—Duration of effect of subcutaneous injection of 1 ml of 1/1000 solution of adrenaline hydrochloride in representative case of cirrhosis of liver and in most intense and prolonged response observed in 6 controls, after 12 hours incubation

function tests or by the appearances on liver biopsy. Further evidence that no relationship exists between over-all impairment of liver function and the occurrence of fibrinolysis is afforded by the findings in the cases of primary carcinoma in a cirrhotic liver, since in all these cases liver function was grossly disturbed. Ascitic fluid in cirrhosis of the liver is fibrinolytic, but there was no correlation between plasma activity and the presence of ascites. The resolution of ascites with treatment produced no influence on fibrinolysis, nor did clinical improvement in the patient's condition.

The production of fibrinolysis by operation on patients with apparently normal livers is variable. Macfarlane (1937) recorded an incidence of 70% and Imperati (1937) 50%. Each of the 6 patients with cirrhosis subjected to splenectomy showed intensification of the pre-existing fibrinolytic activity. Further the intensity of the fibrinolysis resulting, even allowing for the existence of a preoperative level, was significantly greater than any observed by us after various operations, including splenectomy, on patients with normal livers. In view of the variability of the effect of operation on patients with normal livers we do not consider any such controls satisfactory. This difficulty does not arise with the response to the subcutaneous injection of adrenaline, since Biggs et al. (1947) have shown that this invariably induces fibrinolytic activity in healthy people. The response of the patients with cirrhosis to the subcutaneous injection of adrenaline, even when the presence of spontaneous fibrinolytic activity is allowed for, was not only of significantly greater intensity than that of the healthy controls but also of significantly longer duration. It may well be that further experience with the adrenaline test will show that the results thereof mirror the effects of operation and will permit the detection of those cases of cirrhosis in which fibrinolysis may become of such intensity as to play a part in the production of the hæmorrhage referred to above. The development of multiple petechiæ in case 26 after the injection of adrenaline supports this view.

TABLE IV—INFLUENCE OF CORTICOTROPHIN ON SPONTANEOUS FIBRINOLYTIC ACTIVITY OF PLASMA IN 3 CASES OF CIRRHOSIS OF LIVER

Case no	Sample	Fibrin (mg per 100 ml) after incubation for ½–24 hr			
		½	6	12	24
2	Initial	139	0		
	Fifth day of corticotrophin 10 mg i.v. daily	203	†	203	186
	Six days later	176	0		
17	Initial	209	109	32	0
	Fifth day of corticotrophin 10 mg i.v. daily	229	251	241	180
	Six days later	228	82	0	
31	Seventh day of corticotrophin 120 mg i.m. daily*	256	232	224	212
	A month later	181	0		

* = Day of development of portal vein thrombosis
† = Not done

The intensification of fibrinolytic activity, which is one of the immediate results of operation, appears to pass off in four hours and it is within this period that there is risk of hæmorrhage of the type previously referred to. Within twenty-four hours the spontaneously occurring fibrinolytic activity present preoperatively is inhibited and this inhibition persists for from seven to twenty-one days. It seems that the initial shock phase is associated with increased fibrinolytic activity and the succeeding countershock phase with its abolition. The view that suprarenal cortical activity inhibits spontaneously occurring fibrinolysis is supported by the observations on the 3 patients given corticotrophin. In both cases 2 and 17 there was a significant reduction in fibrinolytic activity on the fifth day of treatment with corticotrophin. Six days after the corticotrophin had been stopped the fibrinolytic activity had returned to the pre-treatment level. Case 31 was first seen on the seventh day of treatment with corticotrophin 120 mg intramuscularly daily, when evidence of portal-vein thrombosis had developed. The fibrinolytic activity of the plasma then was negligible but four weeks later it was intense. Further support is obtained from the observations by Kwaan and McFadzean (1956), who have shown that the administration of corticotrophin will prevent the lysis of clots produced experimentally in the marginal vein of the ear of the rabbit—a lysis which presumably results from release of fibrinolysin. Truelove (1952) found that corticotrophin did not prevent the development of fibrinolysis after either exercise or adrenaline in volunteers, and we have confirmed his findings with adrenaline. His conclusion, however, that adrenocortical activity had no direct relationship to the phenomenon of fibrinolysis cannot apply to spontaneous fibrinolysis in cirrhosis of the liver.

Macfarlane and Biggs (1948) considered that the most obvious function of fibrinolysis was the proteolysis of pathological fibrin deposits, and Mole (1948) suggested that it might be the physiological means whereby fibrin deposits are prevented from forming on the vascular endothelium in health, especially if its source was, as he believed, the endothelium. Portal-vein thrombosis remains a hazard of splenectomy in cirrhosis of the liver and of the administration of corticotrophin in this disease. Eisenmenger et al. (1952) reported its occurrence in 3 patients so treated. In each there is inhibition of spontaneous fibrinolysis and this may play a part in the development of such thrombosis.

The adverse effect of intense fibrinolysis on hæmostasis is manifest, yet it seems that such activity alone may not cause hæmorrhage. For example, in case 3 the clot formed spontaneously from whole blood obtained fifteen minutes after removal of the spleen lysed in thirty seconds and the clot formed by the addition of thrombin to undiluted citrated plasma lysed in less than thirty minutes; yet clinically there was no bleeding. Again, in case 26, after the injection of adrenaline multiple petechial hæmorrhages appeared in the skin, yet equally intense fibrinolysis was provoked by adrenaline in other cases without the development of such hæmorrhages.

The mechanism of production of spontaneous fibrinolytic activity in cirrhosis of the liver remains obscure. Cirrhosis appears to be the only primary hepatic disease in which spontaneous fibrinolysis has so far been reported and biological studies affect their attitude to it, and of giving an exemplary study to its patients in the application of science and logic to an ethical problem Most of my comment here will deal with the committee's views on homosexuality—in part because modern knowledge has added remarkably little to our attitude towards prostitution, and because (judging from the past) no law or recommendation is likely to have any significant effect upon any but the most obviously professional form, but chiefly because it is society's attitude towards homosexuality which calls most urgently for revision today

* * *

There is one scientific omission, moreover, which cannot be overlooked "Homosexual" behaviour is presumably the display, between individuals of the same sex of an imitation of reproductive mating behaviour, which may or may not end in some kind of sham copulation It occurs under ordinary conditions of observation almost universally among immature and segregated and not uncommonly in adult unsegregated, males of most if not all mammalian species, as well as in other bisexual organisms Similar behaviour has been described between human males in every culture of which we have record, without any obvious psychotic from 4½ to 3 cm It was firm, but in the next eight hours it became loose in the vein and had further shortened to 1 cm Six hours later no clot was discernible on transillumination and on histological examination the vein appeared normal with no evidence of thrombus In the remaining 25 rabbits there was considerable but variable fluctuation in the length of the clot for the first seventy-two hours, but thereafter it remained stable It lengthened (average 1 5 cm) in 8 cases it remained the same length in 12 , and in 5 it shortened (average 1 cm) On histological examination a well-formed thrombus was found in each vein Strikingly in all sections evidence of organisation was minimal and at most was restricted to a small segment of the clot In the majority the clot had retracted from part of the wall of the vein, forming a by-pass channel and here the clot surface was covered by endothelium continuous with that of the vessel

Discussion

As was pointed out by Jaques [4] experimental venous thrombosis is difficult to produce in healthy animals The method here reported may have an application in this field

It appears reasonable to suggest that the clots in the veins of the control rabbits stimulated the production of fibrinolysin with consequent lysis of the clots and that corticotrophin inhibited this production This view supports the hypothesis advanced by Kwaan et al [1] that suprarenal cortical activity was responsible for the postoperative disappearance of spontaneously occurring fibrinolysin from the plasma of patients with cirrhosis of the liver They consider that the disappearance of fibrinolytic activity is a possible factor in the development of portal-vein thrombosis in cirrhosis of the liver after splenectomy or during corticotrophin therapy

The inhibition of fibrinolysis may play a part in the genesis not only of postoperative venous thrombosis but also of atherosclerosis, because Duguid [5] whose observations have been confirmed by Harrison,[6] Geiringer [7] and Crawford and Levene [8] holds that the initial phase of development of atherosclerosis is the occurrence of mural thrombi Persistence of such thrombi leads to thickening of the intima and subsequent fatty change produces the typical appearance of this lesion The inhibition of fibrinolysis by suprarenal cortical activity may be a factor in determining the persistence of mural thrombi, and the observations reported here have a value in the experimental investigation of atherosclerosis

Clinical Consequences of Cerebral Anoxia

THE neurological section met on Jan 5, under the presidency of Dr REDVERS IRONSIDE

Dr R S ALLISON (Belfast) referred to hypoxic reactions occurring in medical practice, the chief causes of which were cerebral circulatory failure, dehydration, barbiturate poisoning, and electrolytic imbalance He described an instance of a patient with chronic duodenal ulcer who had been vomiting and taking alkaline powder regularly, and whose confused mental state was related to a fall in cerebral oxygen saturation He emphasised that hypoxic effects in all patients were often mistaken for hysteria When the severity of anoxia was unknown and the patient was still unconscious when seen, it was difficult to forecast the prospects of survival ; but repeated epileptiform fits and sweating were ominous signs, and, if the patient survived, irreversible damage to the nervous system might result in a partial decerebrate state

The principal neurological sequelæ after severe anoxia were hemiplegia, parkinsonism, dysphasia, and visual agnosia Multiple defects in intellectual function were also found in all cases, and constructional apraxia was especially common This might persist after full consciousness had been regained, and interfere with performance if the patient was allowed to return too soon to work

Dr P D BEDFORD (Oxford) drew attention to further clinical states Transient effects of cerebral anoxia included sleep disturbances, nightmares, and somnambulism, and these also occurred in heart-failure, toxæmia and pyrexia some other transient disorders were nocturnal confusion, periodic breathing, organic cerebral reactions, and organic neurasthenia He thought that many of these disturbances were produced in old people by histotoxic drugs which also depressed the respiratory centre and he recommended cautious dosage and preferably replacement by paraldehyde Permanent clinical effects included organic neurasthenia, with symptoms such as lack of concentration and dementia as seen after asphyxial episodes, operations under general anæsthesia or in shock from massive hæmorrhage or coronary occlusion Localised cerebral damage due to focal cerebral infarcts occurred in cor pulmonale Dr Bedford wondered whether personal susceptibility or idiosyncrasy explained why many patients were unaffected by a period of anoxia

Prof A MEYER reported on brains he and his collaborators had examined in 6 cases of cerebral anoxia due to ether and nitrous oxide Cardiac or respiratory arrest had occurred in all cases, varying from 1 to 25 minutes The commonest lesions were necrosis of the third layer of the cerebral cortex, Purkinje cells, striate body, and globus pallidus The reticular zone of the substantia nigra, the corpus subthalamicum, and the dentate nucleus were less commonly affected Surprisingly severe necrosis of the thalamus was observed in 3 cases and it had also been encountered in cases of carbon-monoxide poisoning, hypoglycæmia, and death from hanging

Professor Meyer thought that it should be often possible to differentiate between senile and anoxic changes Selective vulnerability was a complex problem and depended on several factors which might vary between different types of anoxia as well as between individual cases

Dr A L WOOLF was interested to hear Professor Meyer cite epilepsy as a cause of cerebral anoxia He referred to a child with severe epilepsy twenty-four hours after head injury in whom the convulsions were followed by deepening unconsciousness and death in four days The changes in the brain were similar to those described by Professor Meyer in his other cases of anoxia

Dr CECIL GRAY (Liverpool) expressed disapproval at ether and nitrous oxide being nominated as the cause of death in many of the cases mentioned by the speakers ,

Special Articles

TOO MUCH BARBITURATE?

EILEEN M BROOKE
M Sc Lond.
STATISTICIAN, GENERAL REGISTER OFFICE, LONDON

DEATHS in England and Wales due to poisoning by barbituric acid and its derivatives have increased considerably in recent years, until in 1954 they numbered 575 From 1939 to 1945 the annual variation in the number of deaths was small and suicides were not greatly in excess of accidental deaths, the yearly average being

Suicides	Males	16	Accidental deaths	Males	12
	Females	*27*		*Females*	*19*

From 1946 onwards there has been a signal increase in all four groups, shown in table I and fig 1

The average numbers of male and female suicides by barbiturates during 1952–54 were respectively 9 0 and 7 3 times the average for 1939–45, the corresponding figures for accidental deaths were 5 7 and 5 0

During the sixteen years since 1939, the crude suicide-rates for both males and females, when all methods of committing suicide are considered, have tended to oscillate rather than to show a definite upward or downward trend (table II)

The rates for barbituric acid poisoning, however, after remaining fairly uniform up to 1945, have since shown a somewhat rapid upward trend While male total suicide-rates have been consistently in excess of female, the female rates for barbiturate poisoning have been higher than the male from 1943 onwards It seems that a preference has been shown lately for using barbiturates as suicidal agents, rather than some other lethal means

On the assumption that different agents would be used in the same proportions in subsequent years as in 1945, the numbers of suicides expected to be due to each agent have been calculated for 1947, 1950, and 1953, and these "expected" numbers, compared with the actual numbers, are shown in table III

Whereas the number of suicides due to barbiturates might have been expected, on the 1945 basis, to increase by 1954 from 20 to 28 for males and from 35 to 46 for females, the actual increases were from 20 to 161 and from 35 to 230 respectively In 1947 the numbers who used other analgesic and soporific drugs exceeded the expected number, but in 1950 and 1954 the actual numbers were considerably less than anticipated Gas poisoning was also used more frequently in the later years than expected, whereas the numbers of deaths due to the more violent methods—hanging, drowning, shooting, and the use of cutting instruments—were all less It appears, therefore, either that the tendency is for the more active and violent methods of suicide to be abandoned in favour of the more passive methods of barbiturate or gas poisoning, or that an actual reduction has occurred in the suicide rates from more violent methods, but has not been accompanied by a decrease in the rates for barbiturate or gas poisoning Table IV shows the variation in suicide-rates between 1944 and 1954 according to the means used

The medical officer of health for Hampstead, Dr Geffen,[1] commenting on the suicide rates in his Metropolitan borough, made some apposite remarks Investigating the high suicide rate of 1950, he found that, of 86 suicides during 1950–53, 23 used barbiturates He suggests that "some steps should be taken to prevent the ease with which the public can obtain dangerous medicines in lethal quantities" He does not think that "the person who has made up his mind to commit suicide will *sooner or later do so*" *but that* "*it is likely* that the presence of a fatal drug, or an easy means of terminating his life, may cause him to take a fatal step at a time when temporarily his mind is unbalanced"

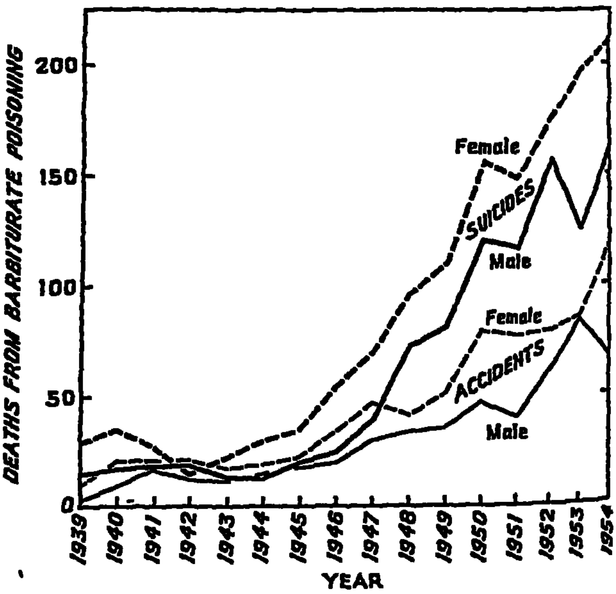

Fig 1—Number of suicides and accidental deaths from barbituric acid poisoning, 1939 to 1954

Dr Geffen also alludes to "fashions in suicides" which may be influenced by publishing accounts of the methods used Coal gas is usually readily available, and, while barbiturates are not freely sold to the public, it will be seen below that they are frequently prescribed under the National Health Service The increase in the suicide rates by these two methods, when rates in which other

1 Geffen D H Report on the Health of the Metropolitan Borough of Hampstead, 1954

movement in the sitting position The natural springiness of the sponge-rubber permits considerable movement and prevents local pressure effects, in fact the "bouncing" effect of the sponge-rubber has given considerable enjoyment to the younger patients and encouraged movements It has not therefore been found necessary to fix the arms, but with more active children the legs have to be lightly secured to the sides of the frame in the manner shown, in order to prevent them from turning over completely on the mattress

Collections have been made for up to three consecutive days, longer periods are not advised because of the risk of pressure-sores around the buttocks due to the lip of the larger hole Usually intermittent twenty-four-hour collections are made (e g, in the study of phenylketonuria) once or twice weekly for balance studies, and shorter timed collections can be made for other diagnostic purposes

It is a pleasure to acknowledge the help and advice of Mr R L Dunn, research and development department, Dunlop Rubber Company, Ltd., Liverpool, by whose 'Dunlopillo' division the mattresses were made I am also grateful to Dr F L Ker, medical superintendent, Little Bromwich Hospital, for permission to describe the binder, to Sister C W Harris for nursing the patients, and to Dr R F Fletcher for the photographs The plastic urinal is manufactured by the Laboratory Glass Blower Company, Valley Works, Lane End Road, Sands, High Wycombe, Bucks

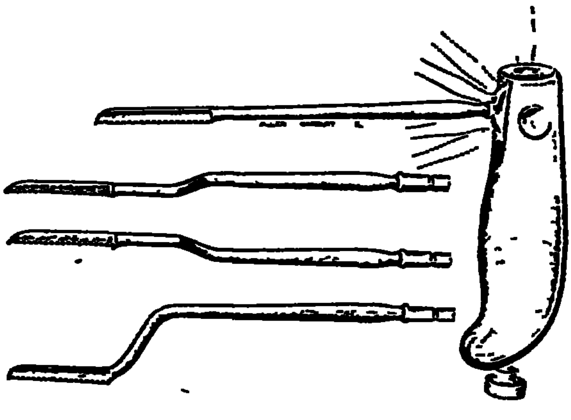
COMBINED NASAL SAW

ONE of the difficulties encountered in the use of the conventional type of nasal saw is that the angle of the blade in relation to the handle does not always offer the correct working position Another difficulty has been that the size and shape of the handle in most of the existing patterns do not always fit with ease to the hand

Messrs Allen & Hanburys Ltd have made, at my suggestion, a combined saw consisting of a special handle and four rapidly interchangeable blades The handle is designed to fit comfortably to the hand and contains a blade socket on a rotating mount which can be locked at any desired lateral angle over a wide range In addition the socket is so arranged that the blade can be used in an "in-line" position with the handle



The set of blades comprises two fine nasal saws cranked right and left, a broad saw with a double row of teeth on a straight shaft, and a Ragnell-type jaw saw

The virtue of this combined saw lies in the handle, which is not only comfortable to hold but also allows the angle of the blade to be easily adjusted to ensure the best working position for the surgeon, with corresponding freedom from fatigue

Professional Negligence

J P EDDY, Q C London Stevens 1955 Pp 146 13s 6d

IN the lectures on which this book is based, Mr Eddy first discusses the general principles of the law of negligence and then deals separately with the different professions The subject is not an easy one, but Mr Eddy has a very readable style and, with few exceptions, he has avoided difficult legal language

In the chapter on doctors, Mr Eddy discusses the standard of care required of medical men, the duty of the doctor to warn the patient of danger which may arise from a particular course of treatment, the legal implications of the confidential relationship between doctor and patient, and the liability of hospitals He ascribes the growth in the number of actions against hospital authorities to four causes—the changed status of the hospitals, the payment of hospital staffs the legal aid system, and the decision of the Court of Appeal in *Cassidy v Ministry of Health* (1951)

Many pages are devoted to a résumé of the more important decisions on the liability of hospitals, including some even more recent than that in the Cassidy case In earlier cases the courts began with the doctor or nurse, if it were shown that he or she had been negligent, then the court would consider whether that person could be regarded as a servant for whose negligence the hospital was liable In Cassidy's case, the Court of Appeal approached the matter rather differently The decision supports the proposition that the hospital itself is under a duty of care to those in its charge, of course, the hospital must act through doctors and nurses, but the hospital cannot escape liability on that ground This approach had indeed been adumbrated by the Court of Appeal in the earlier case of *Gold v Essex County Council*—which is also discussed by Mr Eddy—but it was not the basis of the decision in that case

Logically pursued, this new approach might make it irrelevant to consider the status of the doctor involved in the case, so that the hospital would be liable equally for the negligence of consultants and men under contracts of service The three members of the Court of Appeal were not required to decide that point in the Cassidy case because all the doctors involved were under contracts of service Lord Justice Denning made it plain, however, that he at least was willing so to decide In any event, his judgment makes it clear that the reason why employers were liable for the negligence of servants is "not because they could control the way in which the work was done—they often had not sufficient knowledge to do so—but because they had employed the staff and had chosen them for the task and had in their hands the ultimate sanction for good conduct, the power of dismissal"

All this is implicit in the copious extracts quoted by Mr Eddy, but his own summing up of the Cassidy decision is somewhat guarded and he does not speculate on the possible implications of the decision for the profession Caution on this difficult subject is perhaps the prudent course, however, and many readers will certainly be indebted to Mr Eddy for his clear summary of the cases

A Text Book of Medicine

9th ed Editors RUSSELL L CECIL, M.D, SC.D, professor of clinical medicine emeritus, Cornell University, New York, ROBERT F LOEB, M D, LL D, Bard professor of medicine, Columbia University, New York Philadelphia and London W B Saunders 1955 Pp 1786 £5 5s

FOR twenty-five years this celebrated textbook has enjoyed an enviable reputation on both sides of the Atlantic Despite the great number of authors (there are over 170 contributors) the standard is almost uniformly high and the information up to date If the reader wants to look up the use of 'Versenate' in lead-poisoning, or the therapeutic uses of cobalt, or the indications for surgery in heart-disease, or the present position of pulmonary function tests, the information is there, supported by useful references

TOO MUCH BARBITURATE?

EILEEN M BROOKE
M Sc Lond
STATISTICIAN, GENERAL REGISTER OFFICE, LONDON

DEATHS in England and Wales due to poisoning by barbituric acid and its derivatives have increased considerably in recent years, until in 1954 they numbered 575 From 1939 to 1945 the annual variation in the number of deaths was small and suicides were not greatly in excess of accidental deaths, the yearly average being

Suicides			Accidental deaths		
	Males	16		Males	12
	Females	27		Females	19

From 1946 onwards there has been a signal increase in all four groups, shown in table I and fig 1

The average numbers of male and female suicides by barbiturates during 1952–54 were respectively 9·0 and 7·3 times the average for 1939–45, the corresponding figures for accidental deaths were 5·7 and 5·0

During the sixteen years since 1939, the crude suicide rates for both males and females, when all methods of committing suicide are considered, have tended to oscillate rather than to show a definite upward or downward trend (table II)

The rates for barbituric acid poisoning, however, after remaining fairly uniform up to 1945, have since shown a somewhat rapid upward trend While male total suicide-rates have been consistently in excess of female, the female rates for barbiturate poisoning have been higher than the male from 1943 onwards It seems that a preference has been shown lately for using barbiturates as suicidal agents, rather than some other lethal means

On the assumption that different agents would be used in the same proportions in subsequent years as in 1945, the numbers of suicides expected to be due to each agent have been calculated for 1947, 1950, and 1953, and these "expected" numbers, compared with the actual numbers, are shown in table III

Whereas the number of suicides due to barbiturates might have been expected, on the 1945 basis, to increase by 1954 from 20 to 28 for males and from 35 to 46 for females, the actual increases were from 20 to 161 and from 35 to 230 respectively In 1947 the numbers who used other analgesic and soporific drugs exceeded the expected number, but in 1950 and 1954 the actual numbers were considerably less than anticipated Gas poisoning was also used more frequently in the later years than expected, whereas the numbers of deaths due to the more violent methods—hanging, drowning, shooting, and the use of cutting instruments—were all less It appears, therefore, either that the tendency is for the more active and violent methods of suicide to be abandoned in favour of the more passive methods of barbiturate or gas poisoning, or that an actual reduction has occurred in the suicide rates from more violent methods, but has not been accompanied by a decrease in the rates for barbiturate or gas poisoning Table IV shows the variation in suicide-rates between 1944 and 1954 according to the means used

The medical officer of health for Hampstead, D. Geffen,[1] commenting on the suicide rates in his Metropolitan borough, made some apposite remarks Investigating the high suicide rate of 1950, he found that, of 86 suicides during 1950–53, 23 used barbiturates He suggests that "some steps should be taken to prevent the ease with which the public can obtain dangerous medicines in lethal quantities" He does not think that "the person who has made up his mind to commit suicide will sooner or later do so" but that "it is likely that the presence of a fatal drug, or an easy means of terminating his life, may cause him to take a fatal step at a time when temporarily his mind is unbalanced"

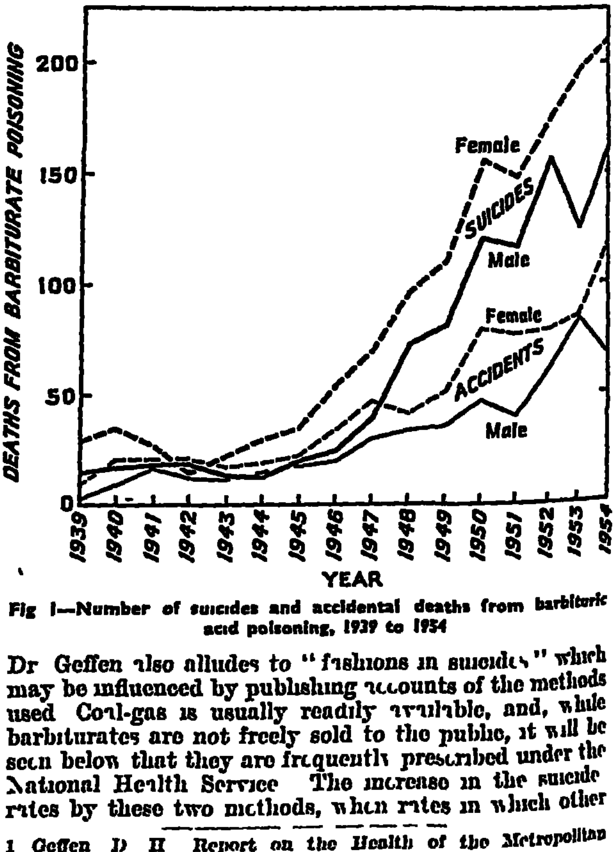

Fig 1—Number of suicides and accidental deaths from barbituric acid poisoning, 1939 to 1954

Dr Geffen also alludes to "fashions in suicides" which may be influenced by publishing accounts of the methods used Coal-gas is usually readily available, and, while barbiturates are not freely sold to the public, it will be seen below that they are frequently prescribed under the National Health Service The increase in the suicide rates by these two methods, when rates in which other

GLAXO INTRODUCE . . .

The food that has everything

In the field of human nutrition the advent of a truly comprehensive food has long been awaited With the introduction of Complan, a new Glaxo food, this important need is at last fulfilled

COMPLAN contains everything the patient needs in the way of essential nutrients to sustain life indefinitely It can be administered either by tube, for which it is ideally suited, or by cup The food is palatable, throws no strain on the digestion, and is extremely well tolerated

The scope for such a food is indeed immense—no less in general practice than in the hospital Complan's two primary functions are to supply the total dietary needs of bed patients unable or unwilling to take food normally and to provide a valuable high protein-vitamin-mineral supplement.

With Complan, the physician can plan the patient's diet in terms of the essential factors of nutrition, for he knows precisely what he is giving Prepared with as much ease as a cup of cocoa and with no more equipment than a table fork, Complan is eminently suitable for hospital and home use alike.

CLINICAL TRIALS

Complan has been extensively tried in a wide variety of general and special units Among these were a neurosurgical unit, a burns and plastic unit, a gastric surgery unit, a mental hospital and a geriatric clinic All have reported favourably on the value of Complan's therapeutic effect—in some cases dramatic—its formula, and its wide acceptance and tolerance by patients All welcomed Complan's valuable time saving features

of risk if it freed them from the burden of child-bearing—often itself fatal But most medical workers would hold that where calculated risks are taken they should in fact be calculated, and the calculation should include that of the patients

Conducted with better facilities, the studies of lithospermum extract are rather less alarming, and with this preparation the risks of clinical trial would not exceed those of any other new and active biological agent Should it prove to be an antigonadotrophin inhibiting ovulation, its use (as **Swyer** points out) might have to be periodically discontinued to prevent derangement of ovarian function, but it is apparently not fully effective in this respect Phosphorylated hesperidin (rehibin), which inhibits the seminal hyaluronidase, offers what seems a less hazardous approach, though its efficacy by mouth has not been proven Local action on the sperms, either before or after they leave the male, seems greatly preferable to alteration of the female endocrine balance (Some of the methods that have been proposed, such as the use of œstrogens to induce tubal spasm which will imprison the ovum, seem to offer almost unlimited possibilities of mischief, and **Zuckerman**'s[34] account of the recent Tokyo conference mentions a chemical which has already produced abnormal fœtuses in a clinical trial) Among the more familiar expedients to which **Swyer** refers, improved occlusive tampons suitable for use under tropical conditions offer at least a partial protection, and work on these is going on Immunological methods of inducing "hostility" to sperms of a given father have so far progressed little, and would probably fall in the category of "luxury" contraceptives It is the poor man (or woman) under bad conditions who most needs and desires an advance in biological methods of controlling fertility We should work more systematically to provide it for him Both in quantity and quality, existing research leaves a lot to be desired,[35] and the "disreputability" of contraception still anachronistically limits the number of first-rate workers

Attention should be drawn, however, to an aspect of this research—or rather of public reaction to it—which is seldom mentioned The people of some Asian and African countries, though they want contraceptive facilities as a right, have reservations which in their position we might share Any suggestion that "the West" was trying to produce a substance with which foodstuffs could be doctored and the fertility of Eastern peoples reduced might release a reaction far more powerful than the Indian Mutiny precipitated by the use of pig grease on cartridges Such suspicions have been voiced, they have all the psychological attributes of an ideal rumour, and unguarded remarks about the beneficial effects of radiation in lowering the population of the world (in countries other than that of the speaker) may lend colour to them For such reasons the spirit in which biologists and doctors approach this problem, and their motives in working on it, may be as important to their ultimate success as is their technical proficiency If, as many believe, we are developing in contraception a human right and a human freedom, it will do no harm to say so fairly often

Annotations

TREATMENT OF LUNG ABSCESS

There are few diseases in which more spectacular therapeutic progress has been made in recent years than in simple lung abscess As recently as 1936, Allen and Blackman[1] reported a mortality of 34% Treatment at that time consisted essentially in external drainage of the abscess, and complications such as empyema and brain abscess were frequent The advent of sulphonamides had no great influence on prognosis, but the technique of surgical drainage improved so much that by 1941 Neuhof and his colleagues[2] were able to record a mortality of only 4% for acute cases, though the mortality for subacute and chronic localised abscesses remained as high as 23% Penicillin produced an even greater change by reducing the number of cases in which surgery was required, and Shoemaker et al[3] now affirm that simple lung abscess should be regarded as a "medical" disease As for ætiology, they hold the generally accepted view that although some simple lung abscesses are caused by trauma or blood-borne infection, or develop from a specific bacterial pneumonia the great majority result from aspiration of infected material from the mouth or upper respiratory passages into the lungs The natural defences of the lower respiratory tract against intrusion from above are relaxed during sleep and other states of unconsciousness, and it is significant that in a considerable proportion of cases of lung abscess there is a previous history of gross dental sepsis, oropharyngeal operation, epilepsy, general anæsthesia, or a bout of drunkenness[3–6] Moreover, Brock et al[7] demonstrated that material introduced into the trachea gravitated into the dependent upper lobe when the subject was lying on his side, and into the dependent apex of the lower lobe when he was lying on his back, and as these are the commonest sites of abscess formation the inference is obvious

Shoemaker et al[3] analysed the results in 67 simple lung abscesses treated between 1950 and 1954 Surgical resection was used in 24—in some of the earlier cases because it was thought to be the best treatment and in others because carcinoma was suspected Confidence in the efficacy of chemotherapy grew with experience however, and it was eventually concluded that this was the treatment of choice, regardless of the duration of the abscess, so that in 1954 resection was performed in only 2 cases, in both because of possible malignancy Only 1 patient in the series failed to respond to adequate chemotherapy, and here the presence of a broncholith provided an explanation Penicillin was considered the best antibiotic, and it was used in all cases with sulphonamide added, unless for some reason the latter was contra-indicated Cavities closed in four to eight weeks, and residual radiographic opacities decreased in size over a period sometimes as long as six months

Gittens and Mihaly[4, 8] evaluated the efficacy of various antibiotics in lung abscess, but they were unable to decide that one was more successful than another Nevertheless, they too concluded that penicillin is the drug of choice because, apart from its small cost, prolonged administration does not entail certain dangers, such as fungal overgrowth in the lungs and disturbance of the intestinal bacterial flora which are associated with the newer

[1] Geffen D H Report on the Health of the Metropolit Borough of Hampstead, 1954

extension of dilated and incompetent lymphatics up to the root of the limb It is possible that all patients with lymphœdema præcox have, before the advent of the cellulitis and lymphangitis to which they are so prone, a dilated and incompetent lymphatic system The subsequent infection, mainly by the streptococcus, obliterates the lymphatic channels and so prevents their demonstration by dye techniques This interpretation could well reconcile the different findings An alternative explanation is that both absence and incompetence of lymphatic channels cause tissue fluid to accumulate and either abnormality may be associated with the clinical picture recognised as lymphœdema præcox

It is becoming clear that the skin and deeper lymphatics are often involved in a variety of vascular diseases So far this has not greatly influenced treatment, but the knowledge is interesting in itself and may lead to therapeutic advances

ABRASION TREATMENT OF ACNE SCARS

THE pimples of acne vulgaris are bad enough as a temporary embarrassment, but the scarring that can follow is a much more serious and permanent disfigurement A great deal of this may be prevented by persistent treatment under experienced supervision, but many cases of acne are neglected because the complaint is almost physiological in adolescence and usually clears up spontaneously In the past, a number of different forms of treatment for acne scars have been suggested, each amounting to some means of superficial destruction of the skin Painting with liquid phenol, followed by "neutralisation" with alcohol, seemed to carry such a disproportionate risk of poisoning that it never became popular Abrasion with sterilised carpenters' sandpaper[1] began a new vogue which has largely been abandoned for fear of foreign-body reactions from implanted silica A refinement of the method is to use rotating abrasive discs or emery wheels A form of mechanical abrasion was suggested as long ago as 1905, when Kromayer[2] introduced small rotating burrs and cylindrical knives for this purpose A modern development has now become so popular in the United States that complete kits for "dermabrasion," as it is called, are widely available The special features of the method[3] include the use of an electric motor producing 12,000 r p m, a range of small wire brushes held with the axis of rotation at right angles to the surface of the skin, and refrigeration with ethyl chloride, which serves both as local anæsthesia and skin hardener Rapid evaporation of the ethyl chloride is maintained by a continuous stream of air 'Freon 114,' which is dichlorotetrafluoroethane, has recently been used[4] instead of ethyl chloride, because it is said to be non toxic, it is non-inflammable, and it is not an anæsthetic on inhalation

Some reports of the results of this treatment were very enthusiastic and were given wide publicity in America One report said that the results are so good that no patient should be refused treatment The American Medical Association's committee on cosmetics called for a report on the method, and this was prepared by Rattner and Rein[5] They state that a high degree of cosmetic repair can be obtained in some cases, but "the results of treatment are usually good rather than dramatic" and they are unpredictable in an individual case The commonest complaint—namely, "dilated pores"—cannot be improved, nor can very wide or deeply pitted scars be greatly modified Their own experience has led them to advise against this treatment in 40–60% of those applying for it Disastrous results have been rare Small horny inclusions or milia form a common but temporary complication Infections have not been troublesome, but in some cases erythema or pigmentation has persisted for some months after treatment Some slight scarring has been seen, but this has responded to further abrasion and no cases of keloidal scarring have been reported This absence of scarring is perhaps the most surprising feature of the method One paper[6] insists that it is possible "to plane down almost to subcutaneous fat and still have noncicatricial healing"

There are only a few places in this country where this treatment is being tried, and it is unlikely that it will ever become a routine matter in our dermatological out patient departments It seems to be a method of value for selected cases of scarring from old acne, chickenpox, or other causes Less enthusiasm is likely for some of its suggested uses, such as the treatment of pigmented lesions and keratoses where histological control is desirable The treatment may be most sought after by patients for whom anything short of miraculous restoration would be inadequate, and who are perhaps rather obsessional about their appearance Indeed, it is in the selection of cases that Rattner and Rein urge most caution It has long been a dermatological paradox that those most seriously blighted by skin disease seem least concerned with their appearance the victims of what are now old-fashioned degrees of lupus vulgaris were often less apparently perturbed than the young man with relatively insignificant scars of acne

FAT AND FERTILE

IN a contribution to the proceedings of the Third International Congress of Nutrition, Widdowson[7] made some stimulating comments on reproduction in relation to obesity She stated that fat women (whether prediabetic or not) had large fat babies who grew big, reached an early puberty, still ahead of the field, and in due course completed the cycle by becoming fat mothers The additional risk which their obesity conferred in pregnancy (largely that of toxæmia) was compensated in the puerperium by the facility with which they fed their children, for the large women with large breasts pro duced more milk than their slender sisters, even to the extent of having lactorrhœa[8] It is safe to say that much of this is in opposition to what many clinicians believe Thus, it is widely held that the fat child is likely to be sexually immature, or late to mature Spence,[9] discussing obesity accompanied by delay in the onset of puberty, noted that nearly all these patients were suffering from simple obesity (though a craniopharyngioma had to be excluded) Yet there is now much evidence which seems to refute the very existence of such an association Wolff[10] has published the most recent of several studies all of which suggest that the obese girl reaches puberty no later and probably earlier than normal The opposite impression may have grown from wide acquaintance with the rare but more publicised endocrine disorders associated with the names of Frohlich and Cushing, and also from a knowledge that obesity and hypomenorrhœa are commonly associated in young adults At least, such evidence as there is (and there is little) goes to show that women with simple obesity may often have amenorrhœa which can be relieved by weight reduction Swyer[11] described irregular or scanty periods in overweight women, in whom restriction of diet restored menstrual regularity and improved fertility From a different approach, Rogers and Mitchell[12] found that a

TOO MUCH BARBITURATE?

EILEEN M BROOKE
M Sc Lond
STATISTICIAN, GENERAL REGISTER OFFICE, LONDON

DEATHS in England and Wales due to poisoning by barbituric acid and its derivatives have increased considerably in recent years, until in 1954 they numbered 575 From 1939 to 1945 the annual variation in the number of deaths was small and suicides were not greatly in excess of accidental deaths, the yearly average being

Suicides	Males 16		Accidental deaths	Males 12
	Females 27			Females 19

From 1946 onwards there has been a signal increase in all four groups, shown in table I and fig 1

The average numbers of male and female suicides by barbiturates during 1952–54 were respectively 9 0 and 7 3 times the average for 1939–45, the corresponding figures for accidental deaths were 5 7 and 5 0

During the sixteen years since 1939, the crude suicide-rates for both males and females, when all methods of committing suicide are considered, have tended to oscillate rather than to show a definite upward or downward trend (table II)

The rates for barbituric acid poisoning, however, after remaining fairly uniform up to 1945, have since shown a somewhat rapid upward trend While male total suicide-rates have been consistently in excess of female, the female rates for barbiturate poisoning have been higher than the male from 1943 onwards It seems that a preference has been shown lately for using barbiturates as suicidal agents, rather than some other lethal means

On the assumption that different agents would be used in the same proportions in subsequent years as in 1945, the numbers of suicides expected to be due to each agent have been calculated for 1947, 1950, and 1953, and these "expected" numbers, compared with the actual numbers, are shown in table III

Whereas the number of suicides due to barbiturates might have been expected, on the 1945 basis, to increase by 1954 from 20 to 28 for males and from 35 to 46 for females, the actual increases were from 20 to 161 and from 35 to 230 respectively In 1947 the numbers who used other analgesic and soporific drugs exceeded the expected number, but in 1950 and 1954 the actual numbers were considerably less than anticipated Gas poisoning was also used more frequently in the later years than expected, whereas the numbers of deaths due to the more violent methods—hanging, drowning, shooting, and the use of cutting instruments—were all less It appears, therefore, either that the tendency is for the more active and violent methods of suicide to be abandoned in favour of the more passive methods of barbiturate or gas poisoning, or that an actual reducti has occurred in the suicide rates from more viol methods, but has not been accompanied by a decrea in the rates for barbiturate or gas poisoning Table I shows the variation in suicide rates between 1944 a 1954 according to the means used

The medical officer of health for Hampstead, D Geffen,[1] commenting on the suicide rates in his Metr politan borough, made some apposite remarks Invest gating the high suicide rate of 1950, he found that, 86 suicides during 1950–53, 23 used barbiturates H suggests that "some steps should be taken to preve the ease with which the public can obtain dangero medicines in lethal quantities" He does not think th "the person who has made up his mind to comm suicide will sooner or later do so" but that "it is like that the presence of a fatal drug, or an easy means terminating his life, may cause him to take a fatal ste at a time when temporarily his mind is unbalanced

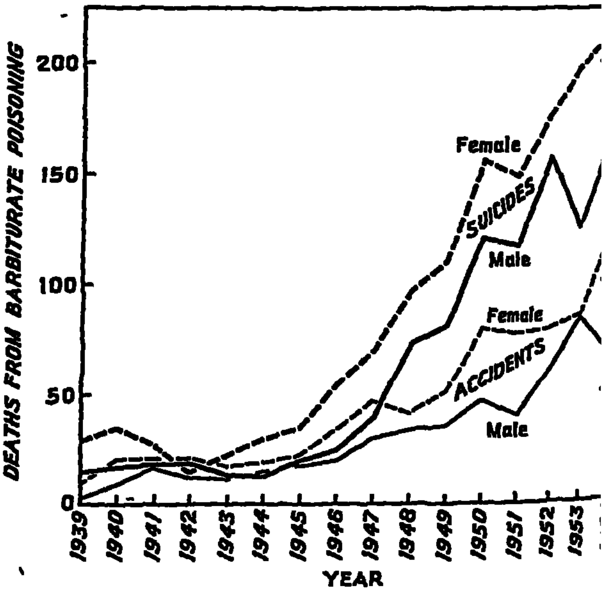

Fig 1—Number of suicides and accidental deaths from barbitur acid poisoning, 1939 to 1954

Dr Geffen also alludes to "fashions in suicides" whic may be influenced by publishing accounts of the method used Coal gas is usually readily available, and, whil barbiturates are not freely sold to the public, it will b seen below that they are frequently prescribed under th National Health Service The increase in the suicide rates by these two methods, when rates in which othe

Points of View

A MATTER OF SCIENCE AND ETHICS

Reflections on the B M A. Committee's Report on Homosexuality and Prostitution *

ALEX COMFORT
M A , M B Camb , Ph D Lond D C H
HON RESEARCH ASSISTANT, DEPARTMENT OF ZOOLOGY, UNIVERSITY COLLEGE, LONDON

THE Departmental Committee now taking evidence on the laws which affect homosexuality and prostitution is a potentially important body In the legal interpretation of sexual behaviour the psychological and biological sciences have for some years been increasingly persistent interrupters from the floor, and this committee is one of the first, in England, to invite them, together with their opponents, on to the platform Like most interrupters so treated, some workers who have much to contribute to the subject have fallen silent many of them have scientific scruples against presenting as evidence what they know to be only opinion But this is a field where the law has long been formed by disturbed minorities, and these scruples are not shared by the opponents of social science

The most important testimony which the committee requires to consider comes in all probability, not specifically from medicine, or even from psychiatry as it is usually understood but from comparative human biology on the one hand, and the social psychology of prohibitive legislation on the other But medicine has a number of important comments to make and doctors—who should, no doubt, be both human biologists and social psychologists—have a chance of being heard on the occasions when "scientists" are being shouted down by common sense, practical geoplanarians appealing to the self evident As there will be no lack of Wilberforces in any such debate, it is clearly someone's business to accept the unpleasantness of being a Huxley

A number of medical bodies are, in fact, giving their views One of these is a special committee set up by the council of the British Medical Association It has just made public the evidence which it proposes to submit, in the form of a report, accompanied by some well-calculated publicity

There are two reasons which make this document worthy of separate discussion The first is political A report endorsed by the B M A might easily turn out to be a microcosm either of the departmental committee's ultimate findings, or of future legislation The considered views of such professional bodies have great attractions for politicians facing unpopular topics the B M A is a conservatively inclined body with a high lobbying potential, which can be set as the exponent of the practical and human in contrast to the extremist or "egg-headed" conclusions of science There is nothing in its title or record to alarm the most disturbed or anti intellectual Member of Parliament, he may never have met a social anthropologist, but he has often met a doctor or two A Minister forced to advocate some changes in the law, unwilling to make many, and faced with an organised and paranoid minority campaign against any at all, will look instinctively for a body, quotable in support of his intention, to which the word "responsible" can be applied

One reason for the importance of the report, then, is that it could provide an opportunity for intelligent medical opinion to comment on the basis of new knowledge, and to encourage the reform of laws which are widely held to be bad There is, however, another Under the influence of modern research and thought, the psychology of law and government is undergoing changes as radical as is the psychology of individual behaviour science is beginning to assume the duty of replacing political ideology with research Our own generation has before it two excellent object lessons in the interplay of emotion, fact, reason, and prejudice in legislation, and of the relation between law-making and personality structure one is the attempt to abolish the death penalty, and the other the attempt to reform the law regarding sex offences In each case there are superficially substantial arguments on both sides, in each case there is intense emotional motivation on both sides, and in each case there are signs of a bimodal distribution of opinion by personality type, one type being commoner among legislators and executive officers, the other among social scientists This is a fascinating and important study—terrifying to those who think that legislatures can be trusted to accept expert advice, or that experts can be trusted to govern It is therefore intensely interesting to see how medical opinions, official and unofficial, scientific and administrative, distribute themselves on this scale In this respect, the B M A 's committee is offering itself for study by its sociological colleagues

* * *

A report of this kind was bound to be difficult to write One source of difficulty is evident if we compare the two matters with which it was to deal Prostitution is a practice which may offend but its discussion disturbs only those who are disturbed by sexuality in general Its control, and even its merits, can be, and have been, discussed with a realism bordering on the cynical Homosexuality is quite another matter. The reaction of our culture to it is so violent, and so disproportionate to any demonstrable importance of the behaviour concerned, that even if a committee is itself quite unaffected by this reaction (an unlikely event, if it is representative) it is bound still to decide how much insight it ought to try to give to those it addresses It could be argued that since doctors have no special claim to be arbiters of the *mores* of their culture, rational or irrational, such a committee should take the public attitude as it finds it This view, very properly, the committee rejects "Doctors," it says, "can influence, by instruction and example, the development of the moral and social environment of their patients, and discourage them from behaviour which may adversely affect their health" They will do so, no doubt, both from their own common sense and from any special insights they derive from the discipline of human biology In valiantly assuming this duty to an emotionally loaded subject, however, the Committee undertakes the responsibility both of showing what those insights are, and of writing intelligently about their application to ethics, and it has clearly found this no light assumption

This report had the opportunity of doing three things—of indicating the weaknesses and inhumanities of the present law regarding homosexuality, which it does with some success, of showing how modern social product Attempts were made to infect some egg albumen artificially with salmonella organisms To produce comparable conditions, it was important to contaminate the centre of the crystals, and to do this albumen had to be dissolved, infected, and re-crystallised Unfortunately, the resultant crystal formation was so different from the original albumen crystals that this method was abandoned All experiments were thereupon carried out on imported crystals known to be heavily infected with *S thompson*

---

* The report was issued on Dec 16, and a long summary appeared in the Supplement of the *British Medical Journal* for Dec 17, 1955 It was prepared as a memorandum of evidence for the Departmental Committee, by an expert committee (set up by the council of the British Medical Association) whose members were Dr RONALD GIBSON (chairman), Dr T H BLENCH, Dr DENIS CARROLL, Dr T C N GIBBENS, Prof J GLAISTER, M D , Mr AMBROSE KING, F R C S , Dr J A MOODY, Dr DORIS ODLUM, Dr T P REES, Dr S L SIMPSON, and Dr R D SUMMERS with Dr E E CLAXTON as secretary On Nov 4 the council of the B M A agreed that the memorandum should go forward as the report of the committee, for on so controversial a subject it was not to be expected that the profession or any large body within it could be in agreement in detail

The experiments can roughly be divided into six different stages Full details are not given here, but will appear when the full report is published

Certain of the egg albumen crystals were powdered by crushing, and comparisons made between the effect of heat-treatment on this powdered material

First Stage

Initially, experiments were designed to find the effect of a wide range of temperature and time A total of 52 samples of both crystalline and powdered egg-albumen known to be heavily infected with *S thompson* was tested

Results varied considerably, and some samples withstood temperatures of 165°F for 10 hours, and 190°F for 3 hours, without the salmonella organisms being completely killed It was noticed that the relatively low temperature of 130°F for 3 days produced negative bacteriological results At first, the significance of this was not fully realised

Second Stage

Tests were continued to examine the effect of high temperatures of 180°F and 200°F for $^1/_2$–5 hours Initially, the results seemed promising, for periods of heat-treatment of 180°F for $1^1/_2$–2 hours and of $^1/_2$-hour at 200°F gave repeated negative results for both crystals and powdered samples

This experiment emphasised that powdered material was much more easily heat-treated than the crystalline products The significance of this finding increased as the investigations proceeded

Up to this point, all experiments had been carried out in an experimental oven, but difficulties appeared when attempts were made to treat large quantities A heat-processing machine, capable of dealing with 200–300 lb of material at a time was used Heat was provided by hot air, but it was found impossible to maintain in all parts of the chamber an even temperature of 180°F for 3–5 hours There were areas at which the temperature never exceeded 110°F, while at the heat inlet a charring of albumen occurred Quite apart from this difficulty, it was estimated that this process was too costly

Third Stage

The effect of long-continued low temperature was next investigated

Initial experiments showed that heat treatment at 120°F was uncertain, for salmonella organisms persisted after 4 days in approximately 1 out of every 5 samples tested By raising the temperature to 130°F, however, all salmonella organisms were killed *after four days'* treatment

Fourth Stage

The next experiment was designed to test this method (130°F for 1–5 days) in conditions similar to those likely to be experienced commercially Samples of crystalline albumen known to be very heavily infected with *S thompson* were wrapped in 'Cellophane' packets

For each test for every cellophane packet of egg albumen which was *heat-treated, another sample* was set aside for bacteriological examination as a control

The samples to be tested were placed in the centre of (*a*) 1-cwt bag of albumen crystals, (*b*) 100 lb wooden case of albumen crystals, (*c*) 28 lb tin of albumen crystals The results are given in the accompanying table

These results were then checked, using ten samples at each temperature with similar results no organisms survived after 4 days at 130°F with crystalline material, or after 2 days at 130°F with powdered albumen

These large scale experiments and all subsequent ones were carried out in a hot room measuring 11 × 12 × 9 ft As it was a converted refrigeration room, heat insulation was very good, and it was heated during these experiments by three radiant electric heaters An electric fan ensured complete circulation of air The temperature was thermostatically controlled, and a Cambridge temperature recorder was installed outside (see figure)

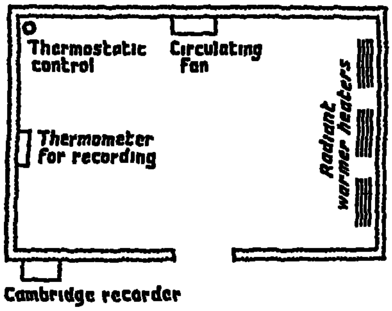

Diagram of the hot room

Fifth Stage

This experiment was designed to test the effect of placing 100-lb wooden containers at various parts of the hot room It was found that each container had to be placed at least 2 ft from the floor, otherwise the hot air circulating did not heat the centre sufficiently When raised 2 ft from the floor, and provided a free air space separated different containers, a temperature of 130°F was reached in the centre of the container within 36 hours, with an air temperature of 110°F (provided the fan was used)

Thus, with 100-lb containers, 36 hours must be added to the time of the earlier experiments

The cost of heating the room with the three electric heaters was roughly *1s* a day

Sixth Stage

The final test was to measure the effect of heat-treatment on solubility

It was found that with the crystalline product 4 days at 130°F was satisfactory but after 5 days at 130°F, changes reducing the solubility were demonstrated Heat-treatment on the powdered material showed less effect on solubility

DISCUSSION

These results suggest that the final solution of the problem of infected egg albumen will probably be mass low temperature heat treatment

To make treatment easier, all material should first be powdered The aim of heat treatment should be to ensure that a temperature of 130°F is maintained in the albumen in the centre of the container for 1–5 days It is estimated that in a *hot room* devised for this purpose, it would be necessary to have an air temperature of 140°F for $5^1/_2$–$6^1/_2$ days after the albumen is first placed in the room It is most important to maintain free circulation of the heated air, and to stand the cases at least 2 ft off the ground

RESULTS OF HEAT TREATMENT OF INFECTED CHINESE EGG ALBUMEN UNDER VARIOUS CONDITIONS AT 130°F

All positive samples yielded *S thompson* or endocrine correlations. The reactions of these various cultures range from complete toleration to intense emotional disturbance, and from admiration to severe punishment for individuals so behaving. Similar behaviour between females, however, only exceptionally evokes any intense reaction.

At no point does the B.M.A. report mention this comparative background. Yet the comparative study of sexual behaviour in man and animals is perhaps the fundamental contribution of modern biology to this whole question. A summary of mammalian work, or even an account of the attitudes of some other human societies, would probably have been more useful to the Departmental Committee than a long appendix describing the effects of evangelism on homosexual persons, while the lack of any paragraph dealing with phylogeny makes nonsense of a good deal of the discussion of causation neither genetics, endocrine imbalance, nor processes of parent-identification contribute detectably to the causation of homosexual play between dogs, sticklebacks, or rats, so far as the literature indicates—though they may begin to do so in higher primates, the complexity of whose sexual behaviour forshadows our own. One might punish these lower animals, but there would be little point in consulting a veterinary surgeon about their behaviour.

* * *

But the real importance of comparative studies is in their effect on our attitude, and I suspect that it is for this reason that they have been omitted.

If the authors of the report were tired of ethical judgments on human behaviour drawn from white rats and Trobriand islanders, they have most reasonable men on their side. Comparative and descriptive studies in animals or in man have no direct ethical meaning. The distribution of homosexuality in mammals and in cultures is not very different from that of fights to-the-death between males as a feature of mating behaviour, yet only the German duellists of the 1930s invoked phylogeny to prove the natural merit of this kind of competition. Nevertheless a background of comparative study does and should condition our response, and that of the Departmental Committee, to the magical propaganda regarding the unnatural, the diabolistic, and the loathsome, which plays such a large part in preventing the sensible discussion of sexual deviations, and even of the normal range of sexual behaviour. However harmful to society homosexual behaviour may be in man, the biologist, surrounded day in and day out by the homosexual activities of his healthy laboratory animals, finds it hard to muster convincing indignation at its unnaturalness.

It would, I think have been extremely valuable to the Departmental Committee's judgment—and, for that matter, my own—if this report had included a serious discussion of evidence that homosexual conduct has, in fact, social or psychiatric ill effects other than those due to the reaction it evokes in society in societies which encouraged it, did it become a self-propagating emotional disability? If, as the B.M.A. Committee believes (on evidence of the kind which has so long bedevilled the attempt to trace an authentic instance of instinct in human psychology) there are "essential" homosexuals, is it beneficial to their mental health to prohibit or discourage their activity? Does the same apply to persons who display both homosexual and heterosexual behaviour? Many would think that psychiatrists with a sufficiently wide comparative insight are among the people best qualified to answer these questions.

The committee says that it proposes to base its advice in ethical matters upon the effects of behaviour upon health and welfare it also devotes much time to the administrative arrangements for treating homosexuals instead of punishing them. The evidence its presents tends to indicate (1) that in man apart from the supposedly "essential" cases which it postulates, homosexuality is, like heterosexuality, a continuously distributed variable, and (2) that while its association with certain forms of psychological upset is evident in many of the individuals who come for treatment, there are probably circumstances under which it is no more a psychiatric problem than any of the wide range of sexual manifestations which may be displayed by "normal" human beings. In regard to homosexual play between adolescents, the committee takes this view it also lays stress on the need to assess each case upon its merits. There is, I believe, no virtue in treating people for symptoms which are not pathological or in punishing them savagely for crimes which are of no social importance, and there is a risk that the courts will grudgingly accord treatment to subjects who engage in homosexual behaviour and are mentally disturbed about it, while discharging the whole weight of frustrated righteousness on those who are not. It is not so long, after all, since adolescent masturbation was solemnly quoted as a cause of mental disorder, blindness, and pimples.

* * *

Medicine could help at this point, if it were willing to risk some legislative unpopularity by pointing out the differences between public law and personal ethics. The B.M.A.'s committee has felt itself unable to recommend that homosexual offences involving neither violence scandal, nor seduction should be recognised as outside the province of the law. It may be right in this, but I cannot help feeling that its views would have been more respected if their presentation and logic had been less confused in the ethical passages of the report. Perhaps the crux of the matter lies in the committee's own summary

> "The apparent increase in homosexual practices and in prostitution is attributable to the weakening of the sense of personal responsibility with regard to social and national welfare in a significant proportion of the population. It is illogical that homosexual practices receive greater condemnation than promiscuous heterosexual intercourse."

One could equally argue that there is a sense in which the increase, if real, represents the reverse of such a weakening, because the climate in which it occurs has sprung largely from the impact of new knowledge on society, leading to a rejection of pontifical and magical regulations upon conduct, and a search, often very confused and beset by rationalisations, for reasons for or against particular modes of behaviour. The teenage boy or the grown man who is no longer disturbed by the memory of a homosexual experiment has not unless he is exceptional, read widely in comparative social anthropology though he may have read Kinsey, or a distortion of Kinsey's findings in the Sunday Press. His lack of disturbance is, to my mind, a gain rather than a loss to the mental health and morale of the future.

I suspect that the author of the passage dealing with salacious posters would even the discrepancy between homosexual and heterosexual offences by increased punishment of the second. Others would incline to do so by presenting to public opinion rational grounds for responsible sexual behaviour. It is not surprising if doctors, like the rest, are confused between these two views they represent two kinds of person, at least as different in their reactions as are homosexual and heterosexual individuals, and probably determined in much the same manner, genetic and environmental. There may even be "essential" punishers and prohibitors. But we should bring the existence of this confusion of counsel to the notice of others explicitly, not implicitly, if our professional sincerity and insight are to be respected.

Relatives have to be interviewed the whole time, not so much with the idea of imparting information as to ascertain the aberration in themselves which precipitated the patient's trouble However, I had to sympathise with the husband who told me how it all began with his daughter's blinking eyes The school nurse said it was a cold, the doctor conjunctivitis, and the optician short sight They went to a specialist in Harpole Street who said it was astigmatism and ordered reading glasses, but another specialist in Wimley Street ordered distance glasses, while a third specialist at the hospital said that no glasses were needed at all "The wife has been confused ever since," he explained

* * *

As a devotee of this column, I may be excused for taking a special interest in Berwick-upon-Tweed, which might suitably have chosen "In England Now" for its motto—at least since the Reform Act of 1885 Before then the citizens must have had great difficulty in knowing when they were and when they were not in England The town changed hands between England and Scotland thirteen times from 1147 to 1482 it then became semi-independent, so that it had to be specially mentioned in all Acts of Parliament Berwick was included in the declaration of war on Russia before the Crimea, but this was forgotten when peace was made It will be interesting to see whether Mr Krushchev travels the Great North Road when he pays his promised visit to this country

Berwick is an anomalous place altogether It has its being in Northumberland but gives its name to a Scottish county Its Royal Border Bridge crosses the Tweed but not the border It is Scottish in speech and in appearance Its football team, Berwick Rangers, play in the Scottish League There has long been a movement for a return to Scotland, but it seems unlikely that this will be achieved For one thing, the difficulty of redrafting all the statutes suggests that Berwick will continue to provide a typical example of British compromise Cynical Scots may take pleasure in pointing out that it is no compromise to leave Berwick a few miles on the English side of the Border, but it has its uses The Scotsman who is wise enough to take the East Coast road to England is offered a gradual introduction to his new environment Strengthened by the sight, as he passes through Berwick, of Scotsmen everywhere, the peripatetic Scots graduate will be helped to withstand the shock, as he journeys further South, of meeting an occasional English doctor

Letters to the Editor

POLIOMYELITIS A BAFFLED LAYMAN

SIR,—As a layman I have recently had to decid whether or not to keep my child away from school aft a classmate had contracted poliomyelitis I learned that paralytic poliomyelitis has a 40% death or disabl ment rate, that the death-rate is highest in the young age groups, that the disease is probably transmitted b personal contact in a narrow stream of the populatio that there are many unrecognised cases which can pa on the infection, and that the chain of infection wa followed through for 31 out of 37 cases in the Isle o Wight epidemic of 1950 I therefore decided to keep m child at home for at least three weeks, arguing that while she might develop the disease as a result of th exposure to infection which she had already experienced she would at least not be exposed to possible infectio from any further cases (recognised or unrecognised which might develop

I am, however, very puzzled about the differen attitudes of the various authorities both in my distric and over the country as a whole

The school doctor here says "keep the children awa from crowded places (e g, cinema, parties)," but apparentl does not go on to make what seems to me the logical extensio by saying that they should be kept away from the crow in which the virus is known to be circulating (i e, school)

At a nursery school in my district mothers were informe when the older sister of one of the little ones had poliomyeliti and told to keep their children at home if they wished However, I was not notified by my daughter's infant school of th case in her class, and in fact subsequently discovered tha there had been a previous case in the school two weeks before In spite of this the headmistress said it is "perfectly absurd" to keep the children away from school Yet in some othe parts of the country, when a case of poliomyelitis occur schools are closed or the parents told to keep their childre at home if they wish

In my area not only does the public health departmen consider it unnecessary to keep children away from school but a health visitor is reported as having told the mothe of a child with poliomyelitis not to tell people what was th matter I cannot believe that a policy of secrecy is righ unless there is absolutely no knowledge of how the diseas is transmitted, and, if my understanding of the medica literature is correct, the position is by no means so black as that

In this district the fathers of both the cases of which we know continued going to work, but when one of my office colleagues contracted the disease the friend with whom he shared a flat was kept from work for three weeks, while my office in London was notified of the case by the local medical officer

Should there not be a consistent policy over the whole country? If medical opinion is too divided for this to be possible, could not the public be told the known facts and left to make their own individual decisions as to what precautions they take [1]

BREAD

THE WIDDOWSON-MCCANCE INVESTIGATION

SIR,—In your leading article of July 30 last you said that nothing in the Sanderson-Wells lecture [2] or in the Widdowson-McCance report [3] had altered your preference for high extraction or National flour as opposed to enriched white flour, and, in support of your conclusion, you quoted figures suggesting that the 70% white flour used in the investigation was in fact not a 70% flour at all, but one approximating to an 80% National flour In your issue of Sept 3 I pointed out that this suggestion was incorrect, and therefore misleading The detailed evidence which you then gave in a rejoinder to my letter or endocrine correlations. The reactions of these various cultures range from complete toleration to intense emotional disturbance, and from admiration to severe punishment for individuals so behaving. Similar behaviour between females, however, only exceptionally evokes any intense reaction.

[3] *Spec Rep Ser med Res Coun Lond* no 287 1954

At no point does the B.M.A. report mention this comparative background. Yet the comparative study of sexual behaviour in man and animals is perhaps the fundamental contribution of modern biology to this whole question. A summary of mammalian work, or even an account of the attitudes of some other human societies, would probably have been more useful to the Departmental Committee than a long appendix describing the effects of evangelism on homosexual persons, while the lack of any paragraph dealing with phylogeny makes nonsense of a good deal of the discussion of causation: neither genetics, endocrine imbalance, nor processes of parent-identification contribute detectably to the causation of homosexual play between dogs, sticklebacks, or rats, so far as the literature indicates—though they may begin to do so in higher primates the complexity of whose sexual behaviour forshadows our own. One might punish these lower animals, but there would be little point in consulting a veterinary surgeon about their behaviour.

* * *

But the real importance of comparative studies is in their effect on our attitude, and I suspect that it is for this reason that they have been omitted.

If the authors of the report were tired of ethical judgments on human behaviour drawn from white rats and Trobriand islanders, they have most reasonable men on their side. Comparative and descriptive studies in animals or in man have no direct ethical meaning. The distribution of homosexuality in mammals and in cultures is not very different from that of fights-to-the-death between males as a feature of mating behaviour: yet only the German duellists of the 1930s invoked phylogeny to prove the natural merit of this kind of competition. Nevertheless a background of comparative study does and should condition our response, and that of the Departmental Committee, to the magical propaganda regarding the unnatural, the diabolistic, and the loathsome, which plays such a large part in preventing the sensible discussion of sexual deviations, and even of the normal range of sexual behaviour. However harmful to society homosexual behaviour may be in man, the biologist, surrounded day in and day out by the homosexual activities of his healthy laboratory animals, finds it hard to muster convincing indignation at its unnaturalness.

It would, I think, have been extremely valuable to the Departmental Committee's judgment—and, for that matter, my own—if this report had included a serious discussion of evidence that homosexual conduct has, in fact, social or psychiatric ill effects other than those due to the reaction it evokes in society. In societies which encouraged it, did it become a self-propagating emotional disability? If, as the B.M.A. Committee believes (on evidence of the kind which has so long bedevilled the attempt to trace an authentic instance of instinct in human psychology) there are "essential" homosexuals, is it beneficial to their mental health to prohibit or discourage their activity? Does the same apply to persons who display both homosexual and heterosexual behaviour? Many would think that psychiatrists with a sufficiently wide comparative insight are among the people best qualified to answer these questions.

The committee says that it proposes to base its advice in ethical matters upon the effects of behaviour upon health and welfare: it also devotes much time to the administrative arrangements for treating homosexuals instead of punishing them. The [illegible] tends to indicate (1) that in [illegible] supposedly "essential" cases which [illegible] sexuality is like heterosexuality, a [illegible] tributed variable, and (2) that [illegible] with certain forms of psychological [illegible] many of the individuals who [illegible] are probably circumstances under [illegible] a psychiatric problem than [illegible] sexual manifestations which may [illegible] "normal" human beings. One could argue [illegible] the increase, [illegible]

[illegible]

SIR,—As the B-vitamin section of the Widdowson-McCance investigations was carried out and reported by me,[1] and as my interpretation of the analytical values for the 70%-extraction flour differs in some important respects from that suggested in your leading article of July 30, it seems desirable that my own views should also be made known

Your article takes no account of the fact that the chemical method I used for nicotinic acid gave considerably higher values for the 70%-extraction flour (though not for the flours of higher extraction) than did the microbiological method employed at the Cereals Research Station When reporting the results of the investigations [1] I gave the microbiological as well as my own values (see p 97), but pointed out (p 108) that the German children's nicotinic acid intakes appeared to be adequate whichever value was used in the calculations

Comparisons of nicotinic acid content should be based on results obtained by the same analytical method Since the values for laboratory milled flours [2] to which you refer were obtained at the Cereals Research Station, it follows that this Station's value for the experimental 70% flour should be taken to compare with them When this is done there is nothing to suggest that the 70% flour used in Germany was considerably richer than other flours of this type Moreover, a comparison between the Cereals Research Station's value of 10 μg per g for the 70% flour used in Germany and their value of 16 μg per g for National 80% flour [3] (see table 12) indicates that the former was in no way comparable with the latter

With regard to vitamin B_1, the method I used gave values for the flours which were slightly higher than the corresponding values obtained at the Cereals Research Station by a different method Both were chemical methods, but, since metabolic studies on the children formed the main subject of the B vitamin investigations in Germany, mine was a procedure applicable to mixed diets, urine, and fæces The Cereals Research Station method was a method designed specifically for flour and was not applicable to other types of biological material

I concluded,[1] from a comparison of my values with data from the general literature (see p 97), that the 70% extraction flour used in the experimental periods was within the normal range with respect to vitamin-B_1 content, but was at the upper end of the range When the Cereals Research Station value of 1 1 μg per g for the German 70% extraction flour (p 98) is compared with their values of 0 7–0 8 μg per g for other flours of this type [2] a similar conclusion is reached Since the Cereals Research Station values were all obtained by the same method of analysis and since their values for laboratory-milled 80% extraction flours were 1 8–2 0 μg per g,[2] and for National 80%-extraction flour 2 4 μg per g,[3] it seems clear that the 70% extraction flour used in Germany was slightly richer than average, but was in no way comparable with an 80% extraction flour as regards vitamin-B_1 content

The riboflavine in the 70% extraction flour used in Germany was not discussed in your leading article, and as an index of the B-vitamin status of flours is admittedly less useful than the concentrations of vitamin B_1 and nicotinic acid, because the difference in riboflavine content between flours of 70 and 80% extraction is relatively small It is of interest however, to note that there was good agreement, on the whole, between my values for the experimental flours obtained by a chemical method and the corresponding values obtained microbiologically at the Cereals Research Station, and that the Cereals Research Station value of 0 47 μg per g for the 70% extraction flour was not only lower than the values of 0 8 μg per g [2] and 0 7 μg per g [3] reported from this station for 80%-extraction flour, but was also lower th the values of 0 6–0 7 μg per g they obtained for oth 70%-extraction flours [2]

Medical Research Council
Department of Experimental Medicine,
Cambridge

W I M HOLMAN

*** There are two issues here

(1) Had the 70%-extraction flour used by McCan and Widdowson an unusually high vitamin-B conten Dr Moran says that its thiamine (vitamin B_1) w "slightly high but still within the range for a 70 flour", but the difference even between his average f the two main consignments (1 15 μg per g) and th figures given by the Ministry of Food (0 7 or 0 8 μg seems to us substantial

(2) Did this flour (as we said) approximate, as regar thiamine and nicotinic acid, to "the National flour this country"? In the table at the end of his lett Dr Moran shows that (according to his analyses) it d not come near the standard laid down for 80%-extracti flour by the Flour Order, but is he prepared to say th National flour itself reaches this high standard? In h current report (1955, p 19) the Government Chemi gives figures for the thiamine content of non-importe National flour (straight run) that range from 1 9 to 2 1 μ but are always below the 2 4 μg specified by the Minist of Food

In view of the apparent difficulty of estimating thiamin in flour, we doubt whether any more exchange of vie will be profitable until Dr Moran, Dr Holman, and th Government Chemist have made, and published, analyse of the same samples of National flour It would b interesting to know precisely how much thiamine, nicotini acid, and riboflavine would now be found in sampl of National flour purchased at random in various par of the country, and how much agreement betwe different analyses can be expected —ED L

CONVULSIONS FOLLOWING PUDENDAL BLOCK BY LIGNOCAINE

SIR,—I read with interest Mr Dutton's article i your issue of Dec 31

It is a great pity that Goldberg's [1] work on the toxicit of lignocaine is so often quoted out of its context

This worker found that when he injected this drug in mice in 0 5% solution, it was equally toxic with procain though it was more toxic when stronger solutions were use Goldberg's LD50 for procaine was 1 02 g per kg, and for ligno caine 1 07 g per kg It is not, however, generally realis that the giving of this dose of any drug to a 20 g mouse i 0 5% solution requires the administration of just over 4 m of solvent—which may be presumed in this case to have bee water This amount of fluid is one fifth of the animal's tota weight, or four times its entire blood volume It will therefo be apparent that the circumstances of these experiments ar in no way comparable to the injection of ordinary amount of local anæsthetic in man, where the total volume of flui given is rarely more than 1/50 of the total blood volume Indeed it would seem possible that at the high dilutions use in Goldberg's experiments the animals succumbed to acut water intoxication before significant amounts of lignocain or procaine could be absorbed

There is a second factor which modifies the toxicit of lignocaine

I found that when this drug was injected prior to thoraco plasty it had virtually no modifying effect on the vaso constrictor action of adrenaline added to its solutions Pro caine, Cyclaine,' and even more so amethocaine antagonis vasoconstriction under comparable circumstances Becau the vascularity of the tissues remains relatively unalte when these latter agents are used the addition of adrenalin to their solutions does not markedly modify their toxic for absorption continues at a rate only slightly slowed by th vasoconstrictor In the case of lignocaine however th adrenaline greatly delays the absorption of the local an thetic drug, whose concentration in the blood stream i

Total (actual)		2238	2694	2885	3178	1432	1680	1586	1865

means were used have decreased, supports Dr Geffen's views Aspirin is another easily obtainable drug and recently suicide-rates for this agent have increased somewhat, though they are low compared with those for the other two methods: this may be because it is not generally known that a sufficiently large quantity of aspirin is lethal and also because of the large number of tablets which must be swallowed to ensure a fatal dose

The actual and expected deaths (suicides and accidents) due to barbiturate and aspirin poisoning during 1946–54 are shown in table v, the expected deaths having been calculated on the assumption that these forms of poisoning account for the same proportion of the total deaths due to poisoning by solids and liquids as they did during 1939–45 (see fig 2)

The sex age suicide-rates from barbiturate poisoning for 1942, 1948, and 1954 are shown in table vi

The increase in rates is apparent in each age-group shown but is more pronounced at ages 45–64 and 65 and over—i e, from the age of the climacteric onwards It is in these age-groups that we should expect to find most of those cases of depression and insomnia for which barbiturates might be prescribed

TABLE IV—CRUDE SUICIDE RATES PER MILLION LIVING, ACCORDING TO THE METHOD USED, 1944–54

Suicidal agent	Males 1944	Males 1946	Males 1948	Males 1950	Males 1952	Males 1954	Females 1944	Females 1946	Females 1948	Females 1950	Females 1952	Females 1954

Jumping from high places	4	4	5	4	3	4	2	3	3	2	2	2
Other and unspecified means	6	7	7	8	7	[illegible]	2	3	3	2	1	2

That barbiturates are dispensed on a fairly large scale is shown from two analyses which have been made of prescriptions on form E C 10 Dunlop et al[2] analysed a sample of 11,435 of these forms comprising 17 301 prescriptions issued during September, 1949, and found 1636 or 9 4% were for barbiturates In an analysis made by the Ministry of Health[3] of 106,295 prescriptions on form E C 10 issued during October, 1954 8 8% were for barbiturates or preparations containing barbiturates The difference between the percentages may have been influenced by the absence of a predominantly rural area from Dunlop's sample, which covered three types only—prosperous residential, industrial, and mixed suburban—as well as by the disparity in size of the samples, but there have also been material changes in prescribing since 1949 and these may provide a better explanation The percentages are believed to be calculated on similar bases but it should be recognised that some of the preparations containing barbiturates contain only small amounts The percentage of all prescriptions in which barbiturates were the sole or principal therapeutic agent in October, 1954, was 6 4, the balance of 2 4% consisting among other things of anticonvulsants, sex hormones, and sedatives and hypnotics other than barbiturates which would be classed in these groups and not as barbiturates

As the samples were for September and October, 1954, the proportion of barbiturates to other drugs as between these two months should not be greatly affected by the seasonal variations in drugs prescribed The selection of September and October as sampling months may, however, have resulted in an unduly high proportion of barbiturates, and had February and March, for example, been selected, no doubt the proportions would have been much less From estimates made by the Ministry of Health, based on samples in different months, the amount of barbiturates prescribed annually during the last few years may have varied between 80 000 and 100 000 lb, but these estimates should be treated with considerable reserve owing to the large sampling errors involved and the difficulty of knowing how far any particular month's prescriptions may be regarded as representative of dispensing during the year

Not all cases of barbiturate poisoning are fatal, and the non-fatal ones may require inpatient hospital treatment, or, if less severe and not requiring overnight care, may be dealt with in the outpatients department In hospital cases it is usually difficult for the statistician to ask for a distinction to be made on a large scale between cases of

drip, and a transient rise in blood-pressure will assure him that the correct treatment is being given

[3] Ministry of Health Personal communication

Following 2 deaths from postoperative collapse which had been treated with noradrenaline drips and high bed-blocking, which at necropsy showed acute heart failure with pulmonary œdema, I employed as a routine in such cases digitalis, aminophylline, and even Fowler's position The results were most gratifying and were certainly not attended by the hazards of bed-blocking and hypertensive drips

In conclusion, I submit the following observations which may give thought to others who are often called on to treat postoperative collapse

(1) Central failure is a more common cause of postoperative collapse than peripheral failure, in those patients who have received infusions during operation This is the result of overloading and (if the infusion is not blood) of cardiac anoxia due to hæmodilution This especially applies to the aged and to those with cardiac disease

(2) The treatment of central failure in mistake for peripheral failure is exceedingly dangerous but the reverse is not so

(3) Hypertensive additives are lethal drugs and, I believe, have very little place in treating postoperative collapse except when hypotensive anæsthesia is employed

(4) A falling blood pressure does not necessarily indicate peripheral failure

(5) *We all appear to be too "drip conscious,"* without *stopping to realise why we are employing them*

London, S W 1 C Landon Smith

HEALTH CENTRE OR GROUP PRACTICE?

Sir,—I am much interested in the correspondence on this subject I should like to strongly support Dr Stephen Taylor (Dec 31) In 1942 I wrote [1]

> "*Health Centres* A glance at the Diagrams shows that here the Doctor has at his immediate beck and call a trained staff He is in close touch with his côlleagues and all the Welfare Workers *Example* Mrs Smith *comes to consult* the Doctor and is *ordered home to bed* Mrs Smith replies 'I *cannot possibly do that Doctor* I have *my* husband and family to *look after*' *The Doctor here is able to reply* 'that is easy take this note over to the welfare workers' room they will fix things up for you' What a vast improvement is here on the decaying past"

Is not this truer even today than when it was written many years ago?

Worthing Harold Leeson

CONSULTANTS IN DERMATOLOGY

Sir—Dr Franklin's letter (Dec 31), in which he states that I am wrong about young trainees qualified to practise both dermatology and venereology (Dec 17), is interesting, but obviously his counter statement refers to only one clinic Surely the fact that the respective groups of dermatologists and venereologists are against dual appointments and the endorsement of this opinion by the Central Consultants and Specialists Committee, proves an overwhelming majority

Dr Franklin's further allegation that higher academic qualifications, whilst required in dermatology, are not in venereology is entirely fallacious *In 1948* some long-established venereologists, just as similar practitioners in dermatology and other special subjects, were accepted as consultants by virtue of their standing *in the* profession and amongst their colleagues although they did not hold higher qualifications Nowadays no applicant for a consultant post in any subject including venereology would be considered by any appointing committee unless he held a higher qualification and my experience as an external assessor on various regional board committees leaves me in no doubt as to this statement I would further challenge Dr Franklin by stating that up and down the country the directors of the majority of venereal disease departments hold higher qualifications

As a past president of the Medical Society for th Study of Venereal Diseases, which publishes what now the only journal on venereal disease in the Engli language, and is *mainly* responsible for postgraduat teaching *in this country*, I cannot recall ever havin enjoyed the presence of Dr Franklin or any of hi assistants at the society's deliberations

"MUNCHAUSEN'S SYNDROME"

Sir,—*The tallish man*, aged 20, with a right faci palsy and a "crew" hair cut, described by Mr Mawson last week, presented himself at the casualty departmen of the West London Hospital on Dec 20

He said *that he had had a right mastoid operation in Dublin* a week before, but he could no longer *afford to pay the hospital* bill and had discharged himself *two days* before and cam over on the boat the previous night He added that he had a headache and that the facial palsy had developed since he had discharged himself from hospital

He had a right endaural incision with the sutures still in position There were several palpable glands on the right side of the neck, but his temperature was 98°F and there was no neck rigidity He was advised to attend an E N T hospital in the morning A penicillin injection was refused ver firmly

"SOCIAL VALUES"

Sir,—As *The Lancet* arrives some five weeks after publication, I do not know whether you have commented on the proposed ban on heroin If the letter in the *Times* of Nov 30 signed by Sir Russell Brain and other eminent signatories has not astonished you as it has me I would like to comment on an important implication of this letter The signatories escape responsibility whether or not the ban on heroin is justified, by saying that the use of heroin must be decided by social values

To me such a view is totally abhorrent The same argument led to attempts to murder the insane in the asylums of Nazi Germany, fortunately frustrated by public opinion led by the Director of Bethel-Bielefeld

Many things may be socially good (and I freely admit that the relief of suffering is) But "love thy neighbour as thyself" is the second Commandment—the first is "love the Lord thy God with all thy heart " Medicine relieves pain because it is *good to do so in the sight* of a Force greater than man secondarily man benefits The motivation is paramount Medicine derives it ethos from natural law, its value is absolute

To admit the social motivation *of* medicine will degrade it to a mere service to the Welfare State (or may be, the Welfare World) *Of course*, all sensible physicians will agree with precautions to prevent heroin addiction, but they cannot admit the *right of the State* (a social organisation) to ban their use of it to relieve pain (a divinely imposed duty) Nowadays social consequences are too often given *as a reason for medical* research and action Only a few weeks ago Dr Bronte Stewart and his colleagues (Nov 26) sought *to justify* their investigation into the relation of coronary heart disease and diet by saying that coronary disease kill or injures 'men our community can little afford to lo

That barbiturates are dispensed on a fairly large scale is shown from two analyses which have been made of prescriptions on form E C 10 Dunlop et al [2] analysed a sample of 11,435 of these forms comprising 17,301 prescriptions issued during September, 1949, and found 1636 or 9 4% were for barbiturates In an analysis made by the Ministry of Health [3] of 106,295 prescriptions on form E C 10 issued during October, 1954, 8 8% were for barbiturates or preparations containing barbiturates The difference between the percentages may have been influenced by the absence of a predominantly rural area from Dunlop s sample, which covered three types only —prosperous residential industrial, and mixed suburban —as well as by the disparity in size of the samples, but there have also been material changes in prescribing since 1949, and these may provide a better explanation The percentages are believed to be calculated on similar bases but it should be recognised that some of the preparations containing barbiturates contain only small amounts The percentage of all prescriptions in which barbiturates were the sole or principal therapeutic agent in October, 1954, was 6 4 the balance of 2 4% consisting, among other things of anticonvulsants, sex hormones, and sedatives and hypnotics other than barbiturates, which would be classed in these groups and not as barbiturates

As the samples were for September and October, 1954, the proportion of barbiturates to other drugs as between these two months should not be greatly affected by the seasonal variations in drugs prescribed The selection of September and October as sampling months may, however, have resulted in an unduly high proportion of barbiturates , and had February and March, for example, been selected, no doubt the proportions would have been much less From estimates made by the Ministry of Health, based on samples in different months, the amount of barbiturates prescribed annually during the last few years may have varied between 80 000 and 100,000 lb , but these estimates should be treated with considerable reserve owing to the large sampling errors involved and the difficulty of knowing how far any particular month's prescriptions may be regarded as representative of dispensing during the year

	F	230	49	469	117	48	244	64	53	121	14	17	82

Not all cases of barbiturate poisoning are fatal, and the non fatal ones may require inpatient hospital treatment, or, if less severe and not requiring overnight care, may be dealt with in the outpatients department In hospital cases it is usually difficult for the statistician to ask for a distinction to be made on a large scale between cases of values ranging from 10 to 14 mg. per day; 1 male patient had values around 18 mg. per day. When chlorpromazine treatment was started in the females the values decreased between the first and eighteenth day to levels near zero, whereas those in the male patient decreased in the first ten days of treatment to levels of 0·6–6 mg. per day. Later the levels in all the patients returned to those before treatment, though chlorpromazine medication was continued. There was a concomitant, but insignificant, decrease of 17-hydroxycorticoid excretion. During the period of extremely low 17-ketosteroid excretion, we sometimes, but not always, found a gradual increase of blood corticotrophin which however returned to normal levels when the 17-ketosteroids in the urine returned to normal.

[3] Ministry of Health Personal communication

Somatotrophic Hormone (S.T.H.)

In patients treated for two months, no acromegalic changes were discerned in photographs taken in profile, but their weight increased noticeably.

In rats treated for over two months with chlorpromazine (10 mg. per kg. body-weight), a definite stunting of growth and development was discernible. 5 female and 5 male rats were given daily injections of chlorpromazine 10 mg. per kg. and their growth curve was compared with that of 5 male and 5 female control rats. Whereas no difference in weight was noted between the initial weights of 30–90 g., obvious impairment of growth became visible later on. Within two months the female control animals reached a weight of 125 g., while the treated animals reached a maximum weight of 95 g. Similar results were obtained in male animals, in which the weight of the controls rose to 200 g., whereas the treated animals remained at 125 g. Then they were given daily 10 R.U. growth hormone subcutaneously, whereupon they attained the weight of the control animals within a further two months.

Thyroid-stimulating Hormone (T.S.H.)

2 patients had their basal metabolic rate (B.M.R.) checked weekly before and during treatment. Before treatment their B.M.R. was + 35% and + 12% respectively. The weekly readings of B.M.R. were as follows:

Case 1 from + 35% to + 20%, + 30%, + 22%, and + 35%.
Case 2 from + 12% to + 18%, + 6%, + 5%, and + 17%.

Thus, there was a slight tendency of the B.M.R. to decrease during the first one to three weeks of treatment. The significance of these results needs further investigation.

Discussion

The mechanism of the endocrine disturbances observed has not yet been clearly defined, since it involves impairment of the hypothalamus or the formatio reticularis as well as peripheral effects which may be humoral, vegetative, or toxic.

The temporary inhibition of the hypothalamus may be explained as follows:

The hypothalamus through its portal veins as well as through its cholinergic and adrenergic fibres regulates the anterior lobe of the pituitary gland. The six tropins cause production of hormones in the peripheral glands by the "push and pull" principle. Thus F.S.H. stands in reciprocal relation to œstrone, L.H. to progesterone and testosterone, corticotrophin to the cortical steroids, and T.S.H. to thyroxine and tri-iodothyronine. These tropins should be called "balanced tropins" since they are permanently kept in balance by the peripheral hormones which they produce. On the other hand, there exist two "unbalanced tropins" which apparently do not produce secondary hormones, but instead exert a direct hormonal effect: thus prolactin produces milk, and S.T.H. has an anabolic effect on bone and muscle growth. It is obvious that neither milk nor muscles can balance their respective tropins.

The theory of the balanced and unbalanced tropins proposed by us would explain the surprisingly high prevalence of lactation in female patients under chlorpromazine treatment. It is possible that a similar effect of growth hormone can be recognised behind the anabolic effect regularly found in all patients under chlorpromazine treatment—namely, rapid gain in weight.

Our hypothesis of the balanced and the unbalanced tropins explains also the temporary fluctuations in hormonal output described by us. It is well known that stunting of the hypothalamus is followed by impaired function of the peripheral hormones. It has been shown in our experiments with chlorpromazine that the imbalance is ended in the case of the balanced tropins within two to three weeks. There is, however, no ready readjustment in the case of the unbalanced tropins.

In addition to the balancing effect within the hypothalamus/pituitary/peripheral gland axis there obviously exist additional peripheral effects which are directly engendered by chlorpromazine. Thus the prolonged effect of progesterone on the rabbit uterus could also be explained as a humoral effect (acetylcholine antagonism), the immediate depression of the 17-ketosteroid excretion as a vegetative effect, and the stunting of growth in rats as a toxic effect (interference with metabolic enzyme systems).

In summary, the manifold effects of chlorpromazine can be largely explained by partial block of the hypothalamus followed by impairment of most of its functions. The effects of hormonal inhibition thus produced in man and animals result in temporary increase of production of the so-called "balanced tropins"—F.S.H. and L.H., as well as corticotrophin and T.S.H. On the other hand there is a prolonged increase of the "unbalanced tropins," especially prolactin resulting in *production of colostrum or galactorrhœa*. In addition to these central effects *there exist peripheral effects* which may be humoral, vegetative, or toxic.

Our thanks are due to our colleagues, Dr. A. Jarus, Mr. A. Evjatar, and Mr. N. Ben Hur, for their help.

Medical School, Jerusalem, Israel.

A RARE COMPLICATION OF CHLORPROMAZINE TREATMENT

SIR,—Gäde and Heinrich[1] have reported the unusual complication of secretion from the mammary glands in three female patients who were taking chlorpromazine. We would like to report a similar occurrence in a virgin aged 21 years.

The patient had long been subject to generalised jerky choreiform movements attributed to thrombosis in or about the basal ganglia following diphtheria at the age of 4½. These movements were made worse by anxiety or emotional disturbance, and disappeared or became less during relaxation, during sleep, or after the ingestion of a moderate quantity of alcohol. Secondary sexual characters were normally developed for her age. Her sexual history was unremarkable. Her periods were regular every twenty-eight days, lasted for three days, and were uncomplicated by pain. She had variable premenstrual tension with some depression.

She was admitted to a neurosis unit on Sept. 10, 1955, and was treated with chlorpromazine 25 mg. t.d.s. Her breasts began to enlarge, and on Oct. 14 began to secrete sufficiently for her to have to wear pads to prevent staining of the clothes. The quantity of daily secretion was unknown, but the fluid was milky and contained fat globules. She failed to menstruate on the expected date (Oct. 30), but menstruated normally at the next period. Gynæcological examination showed no apparent abnormality apart from the secreting breasts. The chlorpromazine was stopped on Nov. 2 and secretion ceased on Nov. 16. Administration was resumed on Nov. 21, and secretion again occurred on Nov. 30 and has continued. Chlorpromazine has helped her movements and disturbed emotional state considerably, and the beneficial action is considered by the patient to outweigh the disadvantage of some breast secretion.

Apart from the three cases already mentioned, no other examples of this effect of chlorpromazine seem to have been reported. This is somewhat surprising in view of the very extensive use of this drug.

Other and unspecified means	6	7	7	8	7	7	2	3	3	2	1	2

That barbiturates are dispensed on a fairly large scale is shown from two analyses which have been made of prescriptions on form E C 10 Dunlop et al [2] analysed a sample of 11,435 of these forms, comprising 17,301 prescriptions issued during September, 1949, and found 1636 or 9.4% were for barbiturates In an analysis made by the Ministry of Health [3] of 106,293 prescriptions on form E C 10 issued during October, 1954, 8.8% were for barbiturates or preparations containing barbiturates The difference between the percentages may have been influenced by the absence of a predominantly rural area from Dunlop's sample, which covered three types only—prosperous residential industrial, and mixed suburban—as well as by the disparity in size of the samples, but there have also been material changes in prescribing since 1949, and these may provide a better explanation The percentages are believed to be calculated on similar bases, but it should be recognised that some of the preparations containing barbiturates contain only small amounts The percentage of all prescriptions in which barbiturates were the sole or principal therapeutic agent in October, 1954, was 6.4, the balance of 2.4% consisting, among other things, of anticonvulsants, sex hormones, and sedatives and hypnotics other than barbiturates, which would be classed in these groups and not as barbiturates

As the samples were for September and October, 1954, the proportion of barbiturates to other drugs as between these two months should not be greatly affected by the seasonal variations in drugs prescribed The selection of September and October as sampling months may, however, have resulted in an unduly high proportion of barbiturates, and had February and March, for example, been selected, no doubt the proportions would have been much less From estimates made by the Ministry of Health, based on samples in different months, the amount of barbiturates prescribed annually during the last few years may have varied between 80,000 and 100,000 lb, but these estimates should be treated with considerable reserve owing to the large sampling errors involved and the difficulty of knowing how far any particular month's prescriptions may be regarded as representative of dispensing during the year

TABLE V—BARBITURATE AND ASPIRIN POISONING

[3] Ministry of Health Personal communication

Somatotrophic Hormone (S T H)

In patients treated for two months, no acromegalic changes were discerned in photographs taken in profile, but their weight increased noticeably

In rats treated for over two months with chlorpromazine (10 mg per kg body-weight), a definite stunting of growth and development was discernible 5 female and 5 male rats were given daily injections of chlorpromazine 10 mg per kg and their growth curve was compared with that of 5 male and 5 female control rats Whereas no difference in weight was noted between the initial weights of 30–90 g, obvious impairment of growth became visible later on Within two months the female control animals reached a weight of 125 g, while the treated animals reached a maximum weight of 95 g Similar results were obtained in male animals, in which the weight of the controls rose to 200 g, whereas the treated animals remained at 125 g Then they were given daily 10 R U growth hormone subcutaneously, whereupon they attained the weight of the control animals within a further two months

Thyroid-stimulating Hormone (T S H)

2 patients had their basal metabolic rate (B M R) checked weekly before and during treatment Before treatment their B M R was + 35% and + 12% respectively The weekly readings of B M R were as follows

Case 1 from + 35% to + 20% + 36%, + 22%, and + 35%
Case 2 from + 12% to + 18% + 6%, + 5%, and + 17%

Thus, there was a slight tendency of the B M R *to decrease* during the first one to three weeks of treatment The significance of these results needs further investigation

Discussion

The mechanism of the endocrine disturbances observed has not yet been clearly defined, since it involves impairment of the hypothalamus or the formatio reticularis as well as *peripheral effects which may be humoral,* vegetative, or toxic

The temporary inhibition *of the hypothalamus* may be explained as follows

The hypothalamus through its portal veins as well as through its cholinergic and adrenergic fibres regulates the anterior lobe of the pituitary gland The six tropins cause production of hormones in the peripheral glands by the "push and pull" principle Thus F S H stands in reciprocal relation to œstrone, L H to progesterone and testosterone, corticotrophin to the cortical steroids, and T S H to thyroxine and tri iodothyronine These tropins should be called "balanced tropins" since they are permanently kept in balance by the peripheral hormones which they produce On the other hand, there exist two "unbalanced tropins" which apparently do not produce secondary hormones, but instead exert a direct hormonal effect, thus prolactin produces milk, and S T H has an anabolic effect on bone and muscle growth It is obvious that neither milk nor muscles can balance their respective tropins

The theory of the balanced and unbalanced tropins proposed by us would explain the surprisingly high prevalence of lactation in female patients under chlorpromazine treatment It is possible that a similar effect of growth hormone can be recognised behind the anabolic effect regularly found in all patients under chlorpromazine treatment—namely, rapid gain in weight

Our hypothesis of the balanced and the unbalanced tropins explains also the temporary fluctuations in hormonal output described by us It is well known that stunting of the hypothalamus is followed by impaired *function of the peripheral hormones* It has been shown in our experiments with chlorpromazine that the imbalance is ended in the case of the balanced tropins within two to three weeks There is, however, no ready readjustment in the case of the unbalanced tropins

In addition to the balancing effect within the hypothalamus/pituitary/peripheral-gland axis, there obviously exist additional peripheral effects which are directly engendered by chlorpromazine Thus the prolonged effect of progesterone on the rabbit *uterus could also be* explained as a humoral effect (acetylcholine antagonism) the immediate depression of the 17-ketosteroid excretion as a vegetative effect, and the stunting of growth in rat as a toxic effect (interference with metabolic enzyme systems)

In summary, the manifold effects of chlorpromazine can be *largely* explained by *partial block of the hypothalamus* followed by impairment of most of its functions The effects of hormonal inhibition thus produced in man and animals result in temporary increase of production of the so called "balanced tropins" F S H and L H, as well as corticotrophin and T S H On the other hand, there is a prolonged *increase of the "unbalanced tropins,"* especially *prolactin resulting in production of colostrum or galactorrhœa* In addition to *these* central effects, there exist peripheral effects which may be humoral, vegetative, or toxic

Our thanks are due to our colleagues, Dr A Jarus, Mr A Eviatar, and Mr N Ben Hur, for their help

A RARE COMPLICATION OF CHLORPROMAZINE TREATMENT

SIR,—Gäde and Heinrich [1] have reported the unusual complication of secretion from the mammary glands in three female patients who were taking chlorpromazine We would like to report a similar occurrence in a virgin aged 21 years

The patient had long been subject to generalised jerky choreiform movements, attributed to thrombosis in or about the basal ganglia following diphtheria at the age of $4^{1}/_{2}$ These movements were made worse by anxiety or emotional disturbance, and disappeared or became less during relaxation, during sleep, or after the ingestion of a moderate quantity of alcohol Secondary sexual characters were normally developed for her age Her sexual history was unremarkable Her periods were regular every twenty eight days, lasted for three days, and were uncomplicated by pain She had variable premenstrual tension with some depression

She was admitted to a neurosis unit on Sept 19, 1955, and was treated with chlorpromazine 25 mg t d s Her breasts began to enlarge, and on Oct 14 began to secrete sufficiently for her to have to wear pads to prevent staining of the clothes The *quantity of daily secretion* was *unknown*, but the fluid was milky and contained fat globules She failed to menstruate on the expected date (Oct 30), but menstruated normally at the next period Gynæcological examination showed no apparent abnormality apart from the secreting breasts The *chlorpromazine* was *stopped on Nov 2, and secretion* ceased on Nov 16 Administration was resumed on Nov 24, and secretion again occurred on Nov 30 and has continued Chlorpromazine has helped her movements and disturbed emotional state considerably, and the beneficial action is considered by the patient to outweigh the disadvantage of some breast secretion

Apart from the three cases already *mentioned, no* other examples of this effect of chlorpromazine seem to have been reported This is somewhat surprising in view of the very extensive use of this drug

means were used have decreased, supports Dr Geffen's views Aspirin is another easily obtainable drug, and recently suicide rates for this agent have increased somewhat, though they are low compared with those for the other two methods this may be because it is not generally known that a sufficiently large quantity of aspirin is lethal and also because of the large number of tablets which must be swallowed to ensure a fatal dose The actual and expected deaths (suicides and accidents) due to barbiturate and aspirin poisoning during 1946–54 are shown in table V, the expected deaths having been calculated on the assumption that these forms of poisoning account for the same proportion of the total deaths due to poisoning by solids and liquids as they did during 1939–45 (see fig 2)

The sex age suicide-rates from barbiturate poisoning for 1942, 1948, and 1954 are shown in table VI

The increase in rates is apparent in each age group shown but is more pronounced at ages 45–64 and 65 and over—i e, from the age of the climacteric onwards It is in these age groups that we should expect to find most of those cases of depression and insomnia for which barbiturates might be prescribed

TABLE IV—CRUDE SUICIDE RATES PER MILLION LIVING, ACCORDING TO THE METHOD USED, 1944–54

Somatotrophic Hormone (S T H)

In patients treated for two months, no acromegalic changes were discerned in photographs taken in profile, but their weight increased noticeably

In rats treated for over two months with chlorpromazine (10 mg per kg body-weight), a definite stunting of growth and development was discernible 5 female and 5 male rats were given daily injections of chlorpromazine 10 mg per kg and their growth curve was compared with that of 5 male and 5 female control rats Whereas no difference in weight was noted between the initial weights of 30–90 g, obvious impairment of growth became visible later on Within two months the female control animals reached a weight of 125 g, while the treated animals reached a maximum weight of 95 g Similar results were obtained in male animals, in which the weight of the controls rose to 200 g, whereas the treated animals remained at 125 g Then they were given daily 10 R U growth hormone subcutaneously, whereupon they attained the weight of the control animals within a further two months

Thyroid-stimulating Hormone (T S H)

2 patients had their basal metabolic rate (B M R) checked weekly before and during treatment Before treatment their B M R was + 35% and + 12% respectively The weekly readings of B M R were as follows

Case 1 from + 35% to + 20%, + 36%, + 23%, and + 35%
Case 2 from + 12% to + 18%, + 6%, + 5%, and + 17%

Thus, there was a slight tendency of the B M R to decrease during the first one to three weeks of treatment The significance of these results needs further investigation

Discussion

The mechanism of the endocrine disturbances observed has not yet been clearly defined, since it involves impairment of the hypothalamus or the formatio reticularis as well as peripheral effects which may be humoral, vegetative, or toxic

The temporary inhibition of the hypothalamus may be explained as follows

The hypothalamus through its portal veins as well as through its cholinergic and adrenergic fibres regulates the anterior lobe of the pituitary gland The six tropins cause production of hormones in the peripheral glands by the "push and pull" principle Thus F S H stands in reciprocal relation to œstrone, L H to progesterone and testosterone, corticotrophin to the cortical steroids, and T S H to thyroxine and tri iodothyronine These tropins should be called "balanced tropins" since they are permanently kept in balance by the peripheral hormones which they produce On the other hand, there exist two "unbalanced tropins" which apparently do not produce secondary hormones, but instead exert a direct hormonal effect, thus prolactin produces milk, and S T H has an anabolic effect on bone and muscle growth It is obvious that neither milk nor muscles can balance their respective tropins

The theory of the balanced and unbalanced tropins proposed by us would explain the surprisingly high prevalence of lactation in female patients under chlorpromazine treatment It is possible that a similar effect of growth hormone can be recognised behind the anabolic effect regularly found in all patients under chlorpromazine treatment—namely, rapid gain in weight

Our hypothesis of the balanced and the unbalanced tropins explains also the temporary fluctuations in hormonal output described by us It is well known that stunting of the hypothalamus is followed by impaired function of the peripheral hormones It has been show in our experiments with chlorpromazine that th imbalance is ended in the case of the balanced trop within two to three weeks There is, however, no read readjustment in the case of the unbalanced tropins

In addition to the balancing effect within the hypo thalamus/pituitary/peripheral gland axis, there obviousl exist additional peripheral effects which are directl engendered by chlorpromazine Thus the prolonge effect of progesterone on the rabbit uterus could also b explained as a humoral effect (acetylcholine antagonism) the immediate depression of the 17-ketosteroid excretio as a vegetative effect, and the stunting of growth in rat as a toxic effect (interference with metabolic enzym systems)

In summary, the manifold effects of chlorpromazin can be largely explained by partial block of the hypo thalamus followed by impairment of most of its function The effects of hormonal inhibition thus produced in ma and animals result in temporary increase of production o the so called "balanced tropins" F S H and L H, a well as corticotrophin and T S H On the other hand there is a prolonged increase of the "unbalanced tropins" especially prolactin resulting in production of colostrum or galactorrhœa In addition to these central effect there exist peripheral effects which may be humoral vegetative, or toxic

Our thanks are due to our colleagues, Dr A Jarus Mr A Eviatar, and Mr N Ben Hur, for their help

means were used have decreased, supports Dr Geffen's views Aspirin is another easily obtainable drug, and recently suicide rates for this agent have increased somewhat, though they are low compared with those for the other two methods this may be because it is not generally known that a sufficiently large quantity of aspirin is lethal and also because of the large number of tablets which must be swallowed to ensure a fatal dose

The actual and expected deaths (suicides and accidents) due to barbiturate and aspirin poisoning during 1946–54 are shown in table V, the expected deaths having been calculated on the assumption that these forms of poisoning account for the same proportion of the total deaths due to poisoning by solids and liquids as they did during 1939–45 (see fig 2)

The sex age suicide rates from barbiturate poisoning for 1942, 1948, and 1954 are shown in table VI

The increase in rates is apparent in each age group shown but is more pronounced at ages 45–64 and 65 and over—i e, from the age of the climacteric onwards It is in these age groups that we should expect to find most of those cases of depression and insomnia for which barbiturates might be prescribed

TABLE IV—CRUDE SUICIDE RATES PER MILLION LIVING, ACCORDING TO THE METHOD USED, 1944–54

Suicidal agent	Males 1944	Males 1946	Males 1948	Males 1950	Males 1952	Males 1954	Females 1944	Females 1946	Females 1948	Females 1950	Females 1952	Females 1954
Poisoning analgesics and soporifics	2	3	7	8	11	10	3	5	10	11	13	14
Poisoning domestic gases	46	46	54	49	52	64	28	36	40	33	34	47
Poisoning, other solids and liquids	7	7	6	5	5	4	5	5	3	4	3	2
Hanging and strangulation	24	32	29	27	25	29	5	8	6	6	5	6
Drowning	19	18	17	16	13	14	11	12	11	10	8	8
Firearms and explosives	12	11	10	9	8	9	*1*	*0*	*1*	*0*	*0*	*0*
Cutting and piercing instruments	15	15	9	9	7	8	2	3	2	2	1	1
Jumping from high places	4	4	5	4	3	4	2	3	3	2	2	2
Other and unspecified means	6	7	7	8	7	7	2	3	3	2	1	2

That barbiturates are dispensed on a fairly large scale is shown from two analyses which have been made of prescriptions on form E C 10 Dunlop et al[2] analysed a sample of 11,435 of these forms, comprising 17,301 prescriptions issued during September, 1949, and found 1636 or 9 4% were for barbiturates In an analysis made by the Ministry of Health[3] of 106,295 prescriptions on form E C 10 issued during October, 1954, 8 8% were for barbiturates or preparations containing barbiturates The difference between the percentages may have been influenced by the absence of a predominantly rural area from Dunlop's sample, which covered three types only—prosperous residential, industrial, and mixed suburban—as well as by the disparity in size of the samples, but there have also been material changes in prescribing since 1949, and these may provide a better explanation The percentages are believed to be calculated on similar bases, but it should be recognised that some of the preparations containing barbiturates contain only small amounts The percentage of all prescriptions in which barbiturates were the sole or principal therapeutic agent in October, 1954, was 6 4, the balance of 2 4% consisting, among other things, of anticonvulsants, sex hormones, and sedatives and hypnotics other than barbiturates, which would be classed in these groups and not as barbiturates

As the samples were for September and October, 1954, the proportion of barbiturates to other drugs as between these two months should not be greatly affected by the seasonal variations in drugs prescribed The selection of September and October as sampling months may, however, have resulted in an unduly high proportion of barbiturates, and had February and March, for example, been selected, no doubt the proportions would have been much less From estimates made by the Ministry of Health, based on samples in different months, the amount of barbiturates prescribed annually during the last few years may have varied between 80,000 and 100,000 lb, but these estimates should be treated with considerable reserve owing to the large sampling errors involved and the difficulty of knowing how far any particular month's prescriptions may be regarded as representative of dispensing during the year

Not all cases of barbiturate poisoning are fatal, and the non fatal ones may require inpatient hospital treatment, or, if less severe and not requiring overnight care, may be dealt with in the outpatients department In hospital cases it is usually difficult for the statistician to ask for a distinction to be made on a large scale between cases of

[3] Ministry of Health Personal communication

appreciable reduction in the 50–70 death rate from diseases of the respiratory system other than cancer, while during the same period the corresponding death rate from lung cancer has increased more than four times The complementary death-rates below age 50 show that the reduction for diseases of the respiratory system other than cancer has been very substantial, while the increase in the corresponding rate for lung cancer, although substantial up to 1945, has since remained practically constant

A similar division has been made of the death-rates for women, but this merely confirms the superiority in its resistance to disease of the respiratory system of the female compared with that of the male The 50–70 death-rate from diseases of the respiratory system other than cancer has fallen by half over the period, while the corresponding death-rate from lung cancer has only doubled In 1953 the 50–70 death-rate from lung cancer for men was over eight times that for women I am not sending the figures for women as I do not wish further to encroach on your space

London, W 1 F L BRADSHAW

URETERIC CATHETERISATION

SIR,—I was very interested in Mr Tresidder's method, described in your issue of Dec 24 For many years, at St Bartholomew's Hospital, gum elastic ureteric catheters have been placed in a cotton container in the form of a tube 1 cm in diameter, and sterilised in a formalin cabinet When the catheter is boilable, however, Mr Tresidder's innovation of Penrose rubber-tubing seems excellent

I would like, however, to sound a note of warning about the plastic ureteric catheter The instrument has not yet been perfected, and the tip is quite liable to break off at the first hole Should this happen in the bladder, the fragment can of course be easily removed with suitable forceps, but if it breaks off in the pelvis of the kidney or ureter the consequences may well be troublesome I have not so far seen this misadventure in the upper urinary tract, but suggest that each catheter should be carefully examined before it is introduced along the cystoscope, and if there is any doubt about its reliability it should be discarded

London, W 1 A W BADENOCH

PRODUCTION OF CODEINE

SIR,—The increased world production of morphine for therapeutic purposes is, according to the report of the U N Permanent Central Opium Board,[1] due to the requirements of codeine This accounts for 80–90% of the morphine manufactured, which amounted to 84 tons in 1954 Although this figure is small compared with that for illicit opium, it is none the less remarkable, since codeine is a drug of such little therapeutic value

Codeine is used universally, but illogically, for the relief of pain

Thus during the last year 200 oz of codeine was dispensed in the London Hospital as tab codein co (800,000 tablets), 190 oz as mixture of aspirin, phenacetin, and codeine, and $31^1/_2$ oz as the linctus This is untidy and extravagant therapeutics because the amount of the drug in two codeine compound tablets or in half an ounce of the mixture contributes negligibly to its analgesic effect, even morphine gr $^1/_6$ given by mouth is less effective than aspirin gr 10[2] Presented in this way codeine only constipates, and the amount in a drachm of linctus codeinæ will not even do this Very little was used for the relief of diarrhœa, and for this purpose there are suitable alternatives

It seems reasonable to end the world production of codeine

London Hospital, E 1 EIRIAN WILLIAMS

BLOOD-TRANSFUSION

SIR,—I fully support Dr Shillitoe's statement (Jan that "experience shows that in reading difficult doubtful agglutinations the opinion of the technici of a few years' experience is greatly superior to that o doctor who has only been doing the job for a few month

At this centre I have been privileged to teach ABO and grouping, preparation of compatible blood, and care a maintenance of a blood bank to several hundred doctors a technicians in the past few years Each course of instructi lasts 5 days[1] As was pointed out in your leading arti (Dec 31), fear of a mismatched transfusion has made jun staff, both medical and technical, unwilling to take t responsibility of declaring compatibility This fear can o be overcome by adequate training and experience, and t technicians and junior pathologists I have met are try very hard to get the experience necessary to give th confidence in their results

As Race and Sanger[2] so aptly put it "to achie accuracy a long apprenticeship of error seems necessa A friendly but silent atmosphere is essential Given silen there is still danger of the mind wandering, this it must n be allowed to do, however routine the tests may be *It is useless to expect reliable blood grouping* and co patibility tests unless staff are given relief from their routi work in order to undertake proper training in simple bloo group work After a basic course, experience is best achiev by repeating the work of a more practised worker Increasi experience will reveal personal shortcomings and the limit tions of the technique and the materials used, and, possib most important of all, teach when to refer problems f advice

When sufficiently experienced, all staff responsible for t supply of compatible blood have one main problem—t lack of time necessary for full safety From the many d cussions during the courses held here it is obvious that high proportion of the urgent requests for blood suppli are due to lack of planning and/or consideration for the path logical laboratory Given the time, and the training, both t technicians and the assistant pathologists can supp compatible blood

Meanwhile, if I required a blood-transfusion I would pu my faith in the trained and experienced technician for th compatibility test Those who perform only an occasion blood grouping, under pressure for an emergency cas cannot hope to possess the technical skill or the abilit of interpretation necessary for the selection of compatib blood Indeed the internal organisation of each un should be such that this is never necessary

Finally it must be stressed that the possession o an academic qualification may automatically comman a certain salary but does not necessarily indicate abilit to undertake compatibility tests Similarly, unqualifie laboratory workers may well have had the necessar training and experience to make their results safe an acceptable This is a decision which can only be mad by the pathologist in charge of the laboratory in th light of his knowledge of the individual, and the issu must not be confused by administrative or politica red-herrings

Regional Transfusion Centre,
Sheffield

I DUNSFORD
Senior Scientific Officer

SIR,—In your leading article (Dec 31) you mentio the Danish cards for simultaneous ABO and Rh grouping[3,4] and quote from the article referred to[3] 6 error out of 15,000 groupings on the cards And you con tinue "Unfortunately an error of 4 per 1000 canno be disregarded when blood grouping is involved "

An error of 6 per 15,000 does not correspond to 4 pe 1000, but to 4 per 10,000 Furthermore, the 6 error

Further experiments are being carried out to ascertain whether the 5½ day method has a sufficient safety margin It will be a great advantage to reduce the time as far as possible, so that the effect on solubility will be slight

Because of the dangers of machines becoming infected during the process of powdering, it is suggested that it should be obligatory on all exporters in China and elsewhere, to powder the product before shipment The 100-lb cases could then be dealt with by this method of heat treatment without any danger The control of this heat-treatment could best be supervised by the medical officer of health at the port of importation in the same way as pasteurised milk is supervised

The bakery and confectionery trades want Chinese crystalline egg-albumen as an ingredient, and it is doubtful whether at present we can depend on this product being handled in such a way in China as to ensure its freedom from harmful pathogenic organisms Therefore, as with milk, we must fall back on some form of pasteurisation to ensure that such pathogens are not consumed by the British public

SUMMARY

Six months' experimental work into the heat-treatment of imported egg-albumen has suggested a practical cheap, and effective method of heat treating bulk supplies of egg-albumen crystals at 130°F for 5½–6½ days

It is recommended that steps be taken to make it obligatory for all imports of egg albumen from China to be powdered and heat treated on arrival in this country

We are grateful to Messrs Goldrei Foucard, Aintree, Liverpool, for their coöperation and generous supplying of material for experiments, and for the experimental facilities provided at their factory Our sincere thanks are also due to Prof D T Robinson and Dr E C Armstrong, of the Public Health Laboratory Service, Liverpool, for performing the extensive bacteriological sampling

Influenza

On Jan 17 influenza-A virus was identified from 2 cases in the Ipswich area New claims for sickness benefit in the week ended Jan 10 were much above average at the Ipswich, Stowmarket Felixstowe, and Woodbridge offices of the Ministry of Pensions and National Insurance There is a lot of influenza-like illness in East Suffolk and virus A may well be responsible

Epidemic Respiratory Illness in Children

As we reported last week, there has been an outbreak of acute respiratory illness among children in Liverpool The total number of cases traced up to Jan 16 was about 300, although many patients treated at home have probably not been included Last week 61 patients were admitted to Liverpool hospitals with a diagnosis of bronchopneumonia A second child died last week and post-mortem specimens have been sent to the M R C Virus Reference Laboratory. It is difficult to know whether the peak of the epidemic has passed but there are many indications that it has Health-visitors are at present seeking information about the health of family contacts

In the past fortnight there was a definite increase in the amount of illness generally in Liverpool, and in the week ending Jan 10, 5700 new claims for sickness benefit were received for the Liverpool area It is rare for the weekly figure to exceed 5000 Figures for all deaths in the past two weeks are as follows

	Week ending	
	Jan 14	*Jan 7*
Total deaths	211	222
Deaths due to respiratory disease		
At all ages	50	56
Under 2 years	5	7

In England Now

A Running Commentary by Peripatetic Correspondents

The New Gentlewoman's Toilet Guide was in the sixpenny secondhand tray. Although it may not have the intrinsic value of the Ebers papyrus, it is much more legible and is equally a mirror of the medical and cosmetic practice of its age The illustrations and a fleeting reference to Garrison Hair Dye suggest the end of the first world war, the text a pre-Coward nostalgic effort to recapture the spirit of Cavalcade I do not claim to keep abreast of current neckline adjectives, but observation without palpation would describe the models to be sagging rather than plunging The Mesopotamian campaign seems to have influenced the nomenclature of toilet preparations Fatima Balsam from a clean saucer was just the thing for an emancipated generation of free-limbed and graceful girls Pummelling it into the bosom for ten minutes every night increased the bust to operatic dimensions If joy through strength was overzealous a slap or two with Zorida Lotion would secure retraction within the limits of the corsage Such an Alice-in-Wonderland touch would be handy nowadays to enhance woolly sweaters in the daytime and minimise the catastrophic insecurity of modern evening dress But whether Madame was coming up or the gown was slipping down appeared to be of no great moment when Mimi Creme achieved the lustre of a snowy-breasted pearl, and Taj Mahal Emulsion had whipped the acne pimples off her back Venus de Milo's marble must have looked adolescent by comparison

The pink and white complexion of an Edwardian intact world could be restored with a couple of bottles of Lait Virginal, made from an old prescription described rather cynically as favoured by the beautiful women at the court of Charles II Whatever disillusionment the war had brought, the situation could be retrieved with a pot of Maiden's Blush "Please send me two dozen" runs one testimonial, but a discreet veil is drawn over the cause for her blushes Do maidens blush today? It's so long since I tried to make one that the section on salts for suppressed gout looks more my line It conjures up mental pictures of the North West Frontier and my paternal grandfather A bookmarker keeps the place for alternate generations, and my big toe tingles expectantly

Even with para-professional privilege and the odd thankoffering of gin at New Year I cannot get a dental appointment for my fillings under a couple of months In the good old days of *The Gentlewoman's Guide* a highly recommended Tooth Stopping Cement kept the family masticating and free from halitosis I suppose it was pushed in with a hat-pin The chapter on self-massage looked promising I tried upward traction on my wrinkled forehead kneading my double chin according to directions, firmly but not violently, smoothing out the bags below my eyes The snag was that without a bottle of Shalimar Enamel the whole dissipated lot flopped back like the flews of a bloodhound I am off to the bookshop in search of *The New Gentleman's Guide*

* * *

The somatic physician who goes digging in the psychiatrists' garden is in for a bewildering experience. It is like groping one's way in a darkroom with both feet off the floor, and as one's eyes become accommodated to delicate shades of grey, one surprise follows another

Ward rounds are particluarly strange Instead of moving from bed to bed inquiring "How are you," I now pass from chair to chair asking for the name of the Prime Minister One patient gave me a cheery "Good morning!", but when I told the psychiatrist, he said "I know, poor soul, she is very disturbed" Several mornings are spent in the production of convulsions and coma, and I find it difficult to keep my thoughts from the many sleepless nights I had doing the opposite Apparently the TV is the biggest boon to psychiatrists since electricity was invented, all programmes from the interludes to "Puzzle Corner" are followed with rapt attention *Punch* is heavily subscribed to, and even in the doctors' mess a pile of copies holds pride of place next to *The Lancet*

The authors often give quotations from the literature of the last century, and when they do not condemn them *they appear to subscribe to them*

Thus, firstly, the emphasis on functional disability and the denial that the "vasomotor system is primarily at fault" tend, I feel, to obscure the importance *of the autonomic* system This may well be not primarily—or even secondarily—deranged But, as research increasingly indicates, it certainly acts as a mediator-effector for corticosubcortical *integration in* all *psychogenic symptoms*, whether they be called hysterical or psychosomatic That is why the *dictum* "I cannot = I cannot will" is confusing, since it brings in volition

Secondly, the reported "striking feature of concreteness of expression" is indeed characteristic, yet not as such, but in the sense of some symbolism *which invariably underlies such* disorders The idea of "dirt," for instance, in its dual sense, is often clearly depicted by psychosomatic skin lesions One can hardly agree with the authors that it amounts to thought disorder (mostly seen in schizophrenia) unless it *had* been *tested* with the usual *proverb tests, &c* *To me, it appears as* part and parcel of the pathogenesis, and I feel that it should simply give food for thought on the psychology and ontogenetic evolution of language rather than be given a sinister significance

Thirdly, *the statement that* the patients wish for amputation "may be regarded as a degree of *self mutilation amounting* to partial suicide" would seem somewhat nugatory unless it is meant to support the view that these patients were mentally ill To call such a wish (not the act !) suicide—even "partial"—is at least *inappropriate*, *for while* on the one hand we know little of the psychology of suicide, on the other the concept of dissociation offers a much more likely psychological explanation

Fourthly, it is suggested that "cases of œdème bleu illustrate the early *stages* of mental illness," and *I think* it is *with this view that the authors* have *raised the neurotic* "inaccessibility to objective evidence and reassurance," to the status of delusions—even though not "frank" ones I think that this is not supported by the facts A psychosis may indeed *mimic all so* called "neurotic" states, but there is no particular reason to consider such states as a prelude to insanity If we agree, as the authors do, that the psychogenic symptoms are vital to psychic *economy*, we cannot mistake the patients' desperate loyalty *to* such symptoms as delusion, while we can appreciate *that the so called "secondary gains"* and "motives" are but the *altera pars* of these symptoms There are as many psychic economics as there are individuals at any given moment, and if they occasionally result in disabilities one cannot readily speak of mental illness

Finally, I would like to join with the authors in their protest against the confusion caused by *that* misnomer, "hysteria" I used, above, *the term* "*the hysterias*", *yet, unlike the schizophrenias*, the epilepsies, and other such "plural" conditions, these possess nothing that is not to be found, rudimentarily at least, in the normal, they are as protean in their psychopathology as life itself

If we all make a point of using terms like "psychosomatic," "immature and unstable personality," "conversion syndromes," and "regression states," there will be no room for so bad a name as hysteria

The National Hospital for Nervous Diseases London W C 1 — G M Jacobides

DANGER—CLINICIANS AT WORK

Sir,—One of the most stimu*lating aspects of medicine* is the inability of its *practitioners to agree on* any topic whatsoever It is no surprise to hardened readers of *The Lancet* to see (Jan 7) that the diets so beloved and acclaimed by our distinguished elders are quite useless in the treatment of peptic ulcer As everybody knows, ulcer is caused by stress which is a *condition found* in prosperous, civilised communities Ulcer is seldom seen in Afghans, who have no worries (and no X-ray machines), and was unknown to our ancestors, who suffered from famine, plague, war, and poverty but never from stress

A few pages further on we read *that the time* honoure abduction splint for paralysis of the *shoulder* muscl should be abandoned Of course it should, and as f repairing hernia by sewing the conjoined tendon to t inguinal ligament (Mr Doran, Dec 24)—it's useless, m dear fellow and if you're thinking of that chap yo *operated on a couple of years ago* forget it ! He isn' *really cured, as you would know if you'd shoved in a fe* radio opaque markers Talking *of radio opaque* marker Mr Doran's lower pair of photographs *repays* a secon glance It will be seen that the outer marker in th conjoined tendon has not only separated from its opposi number in the inguinal ligament, but has moved twic as far from its fellow in the conjoined tendon as it was i *the beginning* How come ? Has the tendon suddenl *doubled in length*, or has the "marker," like any othe foreign body in muscle, *moved around a bit* ?

Don't let's stop There *must* be *plenty of other* useles procedures going on in London What about fracture of the collar-bone ? We usually treat them with som elegant modification of the "three handkerchief sling Why ? Is it to relieve pain ? Try it and see Is it t correct the displacement ? X-ray it and see Why, then Perhaps if I may misquote Pascal, we "have reason *that Reason itself* knows nothing of"

South Mimms, Herts — V J Downie

X RAYS FROM TELEVISION SETS

Sir,—I was interested in Dr Chisholm's query (Jan 7 regarding the possibility of dangerous X-ray emanation from television tubes

Recently I and three other members of our hospita staff carried out experiments on our four television sets Small fast dental X-ray films were placed on the glas immediately in *front of the tubes*, on *the* sides of th *sets, and at other positions up to 2 feet away from th front of the set* A *small disc of metal* was inserted between the sensitive side and the tube, the films being kept in position by 'Sellotape' The films were developed after periods varying from 1 to 8 weeks, and in no cas was there any evidence *of* the films having been sensitised The sets are standard ones with tubes ranging from *14 to 17* inches

This *test seems a fairly easy one to apply*, and as a *result I personally have ceased to worry about* any dangerous television X radiation

Sutherland Dental School,
Newcastle upon Tyne — G E M Hallett

MODIFIED QUECKENSTEDT TEST

Sir,—Dr Belton's *comments* last week cannot be *allowed to pass unchallenged, for apart* from their *theoretical inaccuracy* they contain implications of practical danger His belief that the rise in cerebrospinal fluid (C S F) pressure on jugular compression is due to the slowing of absorption is surely shared by very few This rise in pressure, which takes place within a few seconds, is in *fact* due *to* an increase in the *total* contents of the virtually *inelastic meninges* which enclose blood and nerve tissues as well as C S F Obstruction of the venous outflow whilst arterial inflow continues results in a rapid rise of cerebral blood-volume with consequent rise in C S F pressure The possible alteration in C S F-absorption rate cannot contribute materially to this rapid change

Dr Belton's practical advice is *that jugular* compression *should* be abandoned in *favour of forced* expiration *against* the closed *glottis* by the patient But this manœuvre is precisely that required as a contrast to the effects of jugular compression when one wishes to demonstrate an obstruction to the normal C S F dynamics either in the lateral sinuses or in the *spinal theca*, for it increases intra *abdominal tension, compresses* the howed a confusion of thought to which I was tempted o reply, but at the time it seemed more appropriate o prepare a report on the matter for the Cohen Committee, and this was done However, I now find that at least one other medical journal has apparently accepted your objection as correct As it would be regrettable if the scientific implications of the Widdowson-McCance investigation, unique of its kind, were restricted by any ill-founded criticism, I feel that a further reply is imperative

Before discussing the actual composition of the flours, I should mention that they were not milled under ideal circumstances

At that time (1947–48) the extraction of National flour was 85%, and in the ordinary way the clothing of the sifters in the mills would have been changed for the milling of 70% flour This was impossible, but the milling was carried out under the supervision of experienced staff of the Cereals Research Station, and in the case of the 70% flour several runs were made and the flours analysed before the final flour was regarded as satisfactory The difficulty—as mentioned in the Widdowson McCance report—was to prevent too much powdered scutellum and bran from getting into the flour, this possibility was due to the relatively wide mesh of the silks covering the several flour sieves

Three consignments of flour were supplied (1) a quantity of 70% for the preliminary period only (i e, before the experiment proper began), (2) the first main consignment, and (3) the second main consignment The two main consignments were carefully sampled and analysed at the Cereals Research Station before dispatch. and the results are contained in two letters to Professor McCance, then in Germany, dated May 20, 1947 and Jan 2, 1948 The figures for the 70% (unenriched), 85%, and 100% flours were

Flour extraction	Vitamin B_1 (µg per g)	Nicotinic acid (µg per g)	Iron (mg per 100 g)	Protein (%)
First consignment				
70%	1.2	10	0.99	10.9
85%	3.2	36	2.26	11.8
100%	3.9	48	3.65	11.95
Second consignment				
70%	1.2		1.1	
85%	3.3	30	1.8	
100%	4.2	50	3.6	

When we later analysed for vitamin B_1 a sample of 70% flour from the first consignment that was sent to us from Germany the figure obtained was 1.1 µg per g (report, p 98) The average analysis of the 70%-extraction flour as determined at the Cereals Research Station may therefore be taken as

Vitamin B_1	1.15 µg per g
Nicotinic acid	10 µg per g
Iron	1.05 mg per 100 g

It was on these figures that the degree of enrichment of the other flours used in the investigation was calculated

For a 70–72%-extraction flour the Ministry of Food's *Manual of Nutrition* (1945) gives the following figures

Vitamin B_1	0.7 µg per g
Nicotinic acid	11 µg per g
Iron	1.4 mg per 100 g

In February, 1953, the Ministry adopted the following revised figures

Vitamin B_1	0.8 µg per g
Nicotinic acid	8 µg per g
Iron	1.25 mg per 100 g

All the vitamin-B_1 figures so far mentioned, including those adopted by the Ministry of Food, were obtained by the method in use at the Cereals Research Station since the outbreak of the war[4] The nicotinic acid was assayed by the microbiological method also developed at the station, and in experiments carried out in the last few months, on a wheat mixture similar to that used in the Widdowson-McCance investigation, two flours of 70% extraction milled in different ways gave nicotinic-acid figures of 11.3 and 11.4 µg per g, whilst a 65%-extraction flour gave the figure of 10.2 µg

The conclusion is that the nicotinic acid and iron contents of the 70% flour used in the German investigation were normal for a 70% flour the B_1 content is slightly high but still within the range for a 70% flour Thus, in one of the important papers by Dame Harriette Chick and her colleagues[5] showing the effects of flours of different extraction-rate on the growth of rats the 70% flour had a B_1 content of 1.09 µg per g (the value was determined at the Cereals Research Station) Kent Jones[6] also gives 1.1 µg per g as the average figure for a white flour of about 72% extraction

Your leading article quoted some of the published data on the composition of flour without apparently appreciating how most of these data were obtained The composition of 80% National flour, for example was laid down by the Conference on the Post-War Loaf This definition which forms the basis of the Flour Order, 1953, give the following *minimum* figures for the three nutrients

Vitamin B_1	2.4 µg per g
Nicotinic acid	16 µg per g
Iron	1.65 mg per 100 g

It is of course easy to mill an 80% extraction flour which would have lower levels of these three nutrients, but such a flour would not conform to the prescribed standards for National flour (which in fact is relatively difficult to mill) For this reason the 80% flour quoted by you, which was obtained in a laboratory investigation[7] in which no attempt was made to mill the flour to the Post-War Loaf standards, cannot properly be used as a standard of comparison

Furthermore, one cannot compare data obtained by different methods unless these methods have been shown to give reproducible and identical results on the same sample of material (flour) Thus, the figures for B_1 and nicotinic acid quoted by Dr. Holman in the report were obtained by entirely different methods, the first using adsorption on Decalso with an internal standard and which is held to give higher values than the conventional thiochrome method for flour used at St Albans,[8] whilst the nicotinic-acid figures were obtained by a chemical method in contrast to the microbiological method used for the figures obtained originally on the two consignments of flour

The protein figure of a flour from a given wheat is also an index of its extraction-rate It is our experience that on the average the difference in protein content between a 70% flour and the whole wheat is about 1%, and between 80% and the whole wheat about 0.5% Below, therefore, are listed the characteristics of the 70% flour used in the Widdowson-McCance investigation, with those which would have been expected for an 80% National flour from the same wheat mixture The methods of assay are of course the same for both flours

—	70% flour (as found)	Corresponding National 80% flour
Vitamin B_1	1.15 µg per g	2.4 µg per g
Nicotinic acid	10 µg per g	16 µg per g
Iron	1.05 mg per 100 g	1.65 mg per 100 g
Protein	10.9%	11.5%

From these figures it is certainly difficult to see any justification for your statement of June 30 that the 70% flour was comparable to National 80%-extraction flour

JAMES MEADOWCROFT TURNER

M B Lond, F R C S

Mr J M Turner, consulting orthopædic surgeon to Brighton Municipal Hospital and orthopædic surgeon to the Royal Sussex County Hospital, died on Jan 6 at the age of 52

He was born at Oldham and took his medical training at Guy's Hospital, qualifying in 1920 and taking his M B with honours and distinction in surgery in the following year After holding house-appointments at Guy's he was for a time in general practice in Streatham, but his interest in orthopædics had already been aroused by his work under Trethowan and Lambrinudi, and after holding a clinical assistantship in the orthopædic department at Guy's he became surgical registrar at the Royal National Orthopædic Hospital He took the F R C S in 1928 In the early '30s he settled in Brighton and quickly established a large consulting practice During the late war he served in Persia with the R A M C as an orthopædic specialist, holding the rank of major

R B writes "By nature Turner was shy and retiring, and it was only rarely that he could be persuaded to contribute to the medical journals As an operating surgeon he was conservative, and he preferred to confine his work to the more simple and straightforward cases, but when occasion arose he tackled an exacting and difficult problem with certainty and skill In obscure cases his opinion was invaluable Those who knew him came to depend on his quiet sympathy and surgical skill"

WILLIAM HAROLD ROWE JEREMY

M B Camb, D O M S

Mr Jeremy, ophthalmic surgeon to the West of England Eye Infirmary, died at his home at Pinhoe, near Exeter, on Dec 27 at the age of 46 He was the only son of the late Harold Rowe Jeremy, ophthalmic surgeon to the London Hospital

William Jeremy studied medicine at Cambridge and St Bartholomew's Hospital, and after graduating M B he became ophthalmic house-surgeon at Barts and later house-surgeon at the Royal Westminster Ophthalmic Hospital During the late war he served as an ophthalmic specialist with the rank of squadron-leader in the R A F V R In 1943 he took the D O M S In 1946 he was appointed assistant surgeon to the West of England Eye Infirmary, Exeter, becoming surgeon two years later He was also ophthalmic surgeon to the North Devon Infirmary, Barnstaple, and to the West of England Institution for the Blind in Exeter

M D B writes "Jeremy was always a most conscientious and competent oculist, and soon acquired a flourishing private practice He was at his best in his outpatient work and in the operating-theatre Refractions he endured but never enjoyed, relishing them even less than most ophthalmic surgeons Particularly in his earlier years at Exeter he was keen to try new operations, but in the end he as often as not fell back on old and well-tried methods His patients liked him, and he was essentially friendly and kind-hearted if he had a fault it was that he was too kind and found it difficult if ever he had to break bad news to a patient

"He was a perfect colleague, and my affection for him grew with the years Absolutely loyal, of a genial temper, and with a happy sense of humour, he would have been an asset to the staff of any hospital It is hard to believe that there will be no more of those pleasant breaks on Monday mornings when we three surgeons forgathered for coffee, not really for the sake of the coffee but for the pleasure of being together and of talking about anything or nothing—about a difficult case (and none of us was ashamed to admit before the others that we didn't know the answer), about our patients (William always seemed to have the most extraordinary ones), about infirmary problems and difficulties, or possibly a little scandal, if only we could hear of any Or there were the occasional evenings in Southernhay when he came for a drink, with the inevitable attaché case, and, like Heraclitus, we 'tired the sun with talking and sent him down the sky' until dinner could be kept waiting not a moment longer and William was gonged out"

Mr Jeremy leaves a widow and three young children

OSCAR HILTON

B A, D M Oxfd

Dr Hilton, who was for many years in practice Northwood, Middlesex, died on Jan 8, at the age of 7 He was born in Dundee but was educated in Londo at St Paul's School He was an exhibitioner of Magdale College, Oxford, and after taking his B A with first-cla honours in physiology in 1899 he went to St Thomas' Hospital to complete his medical studies He qualifie in 1902, and held house-appointments at St Thomas and at Great Ormond Street, where he fell under the spel of the late Sir Frederic Still He also held a post at th Children's Hospital, Shadwell, before he settled i general practice on the edge of the Chilterns at Northwood, then a small village With the years Northwoo became a large urban area, and his practice grew an prospered He was one of the founders of the Northwood and Pinner Hospital His experience in general practic led him to publish a monograph on the commone children's diseases, which carried a foreword from Si Frederic Still He retired to Dorset in 1947

"Outside his happy family circle," writes W R "Hilton's two greatest loves were children and hi garden Children could not resist him, nor he them This, combined with his exceptional knowledge o children's diseases, and his broad common sense, were the basis of his success Like all men of character he could sometimes fail He had a short and brusque way on the telephone which occasionally scared away even his friends, but those who knew him loved and forgave this very pardonable fault He will be remembered alwa with affection and gratitude"

D M B, who took over his practice, describes Hilton as "a man of great humanity and charm and endowed with unusual clinical judgment While intolerant of fools and of those who thought themselves much more ill than they really were, to those in trouble or severe illness he gave all his skill and kindness and wise counsel His memory was prodigious, and up to the last there were few details in the family histories of his Northwood patients which he could not recall I used to send him bulletins every three or four months, in which he seemed to delight, and the letters he wrote in answer were full of wisdom and humour"

Dr Hilton leaves a widow, three sons, and a daughter

Professor LERICHE

Mr David Patey writes

May I add a note to your excellent obituary notice on Professor René Leriche to mention the great influence on Leriche of Halsted, an influence probably secondary only to that of Claude Bernard Leriche never seemed to tire of acknowledging this indebtedness as illustrated for example by the famous obituary notice he wrote on Halsted's death, the numerous references in his book *La philosophie de la chirurgie*, and his oration at the Halsted centenary celebrations in Baltimore in 1952 At his first visit to Baltimore as a young man, Leriche was captivated not only by Halsted's contribution to surgical technique in his doctrine of gentleness in the handling of tissues, but also by his surgical philosophy in regarding surgery as a branch of experimental biology

On Leriche's oratory and writing, the charm of which all acknowledge, I once took the opportunity of asking him which French writer had most influenced him I hazarded the guess that it was Flaubert, who was noted for the extreme care with which he polished and repolished every word and sentence, but Leriche told me that this was not so In fact he found Flaubert rather tedious and he said that the writer who had had the greatest influence on him had been Anatole France

Perhaps you will have space for a final characteristic littl story When I was introduced to Leriche at Baltimore in 1952 it was mentioned that we had met at the International Society of Surgeons meeting in Paris in 1951, of which Lerich was president I diffidently added that he would not remember me as I had been just a 'simple soldat" while he was the 'général" Straight away Leriche replied "Il vaut mieux être simple soldat et jeune, que général et vieux" And at once he proceeded to put me at ease with graciousness and charm ever allowed to reach a dangerous level Relatively much arger quantities of it can therefore be tolerated It is probably or this reason that all the accidents which have been eported [2-7] after the use of lignocaine have occurred in atients in whom no adrenaline has been used Mr Dutton's ase is no exception in this respect

It would therefore seem that the best results with ignocaine will be obtained by those who accept 300 mg as a maximum safe dose, and who use the solutions containing adrenaline These conditions in fact impose little limitation on the use of the drug, which is effective for long periods in 0 25% solution Further, though Carnegie and Hewer [8] found that the best vasoconstriction was obtained with 1 250,000 adrenaline it is still possible, in the scalp at least, to obtain pronounced vasoconstriction with as little as 1 1 000,000 There should therefore never be any necessity to exceed the maximum safe total dose of adrenaline which is 0 5 mg

I trust that these facts will help to dispel much of the confusion which has arisen concerning lignocaine, and in future make safer the use of this most valuable agent

A R HUNTER

DOMICILIARY CONSULTATION IN PSYCHIATRIC PRACTICE

SIR,—Dr Denis Leigh (Dec 17) expresses the opinion that the "family doctor is well advised to steer clear of psychotherapy other than simple supportive measures" no doubt for the reason that "the present generation of practitioners is almost untrained in psychiatry" Yet in discussing the figure for outpatient referrals from general practitioners he observes, perhaps rather naively, that "it seems that the general practitioner himself deals with most of his psychiatric patients"

Clearly Dr Leigh regards psychiatry as a field for the expert only This follows inevitably from a view of mental illness, held by many well known psychiatrists, according to which the symptoms are random physical expressions of the disorder, interesting to assess in relation to other bodily events but without meaning in themselves

There is, however, another view of the psychiatric patient, according to which he is a "living," changing person, reacting to other people who are reacting to him, whose symptoms are an essential part of his whole being and a means of communicating his "shut out" feelings and emotions to others, including his doctor This view is frightening to those whose need is to keep everything "scientific"—i e, in their control—and fear recognising their own emotional responses to the patient But it does provide some sort of approach to an understanding of how the general practitioner manages to help his psychiatrically ill patients

All my clinical experience has confirmed that people *do* react to one another, that the patient with a symptom is no exception and neither is his doctor It might be platitudinous to repeat *this were it* not for the existence of an influential body of psychiatric opinion whose need seems to be to deny the existence of these emotional relations, or, admitting to their existence, to deny that they have any significant rôle in the cause or course of the illness

The mechanistic view, which regards the symptom as a manifestation of the patient's 'neuroticism,' precludes acceptance of the view that the symptom is a means of communication, and that its very existence depends on the response which it secures from the "other person" A patient may have asthma, by means of which symptom the "other person" is made aware of his distress and emotionally compelled to act to relieve it The symptom can be the patient's way of saying to the other person 'I am in a desperate state and only your loving concern can save me, but, make no mistake about it, the situation is deadly and if you do not recognise that and treat it as such then I shall die' If a child *is dying of hunger although there is milk beside him* the *spontaneous* reaction is to feed the child before scolding him or even treating him In my view, if he fails to appreciate the emotional significance of the symptom, which I consider the mechanistic view makes inevitable, the psychiatrist may be putting his patient in grave peril

Fortunately most people not expert in psychiatry including general practitioners, do react quite spontaneously to their patients' demands for help and give it to them in one way or another True, not every doctor has the "feel" for helping psychiatric patients fully developed, but a great many do

Here then, is a possible explanation of Dr Leigh's puzzling referral figures When one remembers that minor psychiatry represents a third of all general practice it is encouraging to realise that the rank and file of our profession can and do help their patients—even their neurotic ones I wish to associate myself with the views expressed in the excellent letters by Dr Balint and Dr Hopkins (Dec 31), that general practitioners can and should be helped to develop their innate capacities for psychotherapy, for they alone have the numbers sufficient to cope with the needs

London, N W 3

N CHISHOLM

DANGERS OF RAISING FOOT OF BED

SIR,—Raising the foot of the bed is undoubtedly of value in true peripheral circulatory failure (from hæmorrhage or vasomotor collapse) or in profound anæmia where cerebral anoxia is causing distress Under these circumstances, bed blocking aims at increasing venous return and hence cardiac output *from a healthy heart* and/or increasing cerebral blood flow Before the use of infusions and controlled respiration, bed-blocking as a measure of resuscitation in postoperative collapse was both safe and effective With the advent of both these adjuncts to surgery, however, I submit that bed-blocking in a patient who has received an intravenous infusion with or without controlled respiration is a dangerous if not on occasions a lethal procedure

The difficulty of estimating blood-loss during an operation tends to make replacement therapy err on the side of excess Furthermore, controlled respiration changes a normal negative thoracic pressure to a positive one, causing a greater or lesser degree of venous pooling in the great subthoracic venous tree During an operation, these two factors may well act in opposition, thus maintaining a relatively normal physiology When, however, voluntary breathing becomes established and the patient returns to the ward, the change to a normal thoracic pressure will release the venous pool, and may, in a heart whose reserves are limited by disease or old age cause incipient right sided heart-failure In a case of this nature, bed blocking may tip the balance into severe acute cardiac failure, which may be unrecognised and fatal

The first indication of central failure will be a falling blood-pressure and a rising pulse We have all been taught that this state of affairs in a postoperative patient represents peripheral failure, for which bed-blocking is part of the treatment It may of course be peripheral failure, but if it is treated as such when it is in fact central failure, it will almost certainly be fatal

The practical aspect of all this is fairly obvious It is not easy to distinguish central from peripheral failure in the semiconscious or unconscious patient More often than not, a drip trolley is ready by the time the house surgeon arrives, and treatment aimed at combating peripheral failure is rigorously pursued without a complete appraisal of the situation The rather more imaginative houseman may well use hypertensive additives in the

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on Jan 9, with Prof Stanley Graham, the president, in the chair, the following were admitted fellows of faculty

Ali Muhammad Nasim Almaly, William Brodie, W D Roberts

College of General Practitioners

Butterworth Gold Medal—The subject for this year's essay is the Care of the Elderly in General Practice Essays should be sent, not later than Sept 17, to the chairman of the awards committee of the college, 14, Black Friars Lane, London, E C 4, from whom further particulars may be had

Central Middlesex Group H M C

Dr Peter Friedlander has been awarded a prize of £50 from the research fund of this group for his thesis on the physiological response of the stomach to fat in duodenal ulcer The work of Dr J S Crawford on obstetrical anæsthesia was commended

Microcirculatory Conference

The theme of the third Microcirculatory Conference, which is to be held on April 3, at Milwaukee, Wisconsin, will be regulation of blood flow Further information may be had from the chairman, Mr George P Fulton, PH D, department of biology, Boston University, 675, Commonwealth Avenue, Boston 15, Massachusetts

Child and Family Psychiatry

The department of child psychiatry of the Ipswich Group Hospitals is holding a refresher course on this subject from April 9 to 13 Further information may be had from 11, Fore Street, Ipswich

Oliver Prize

The 1955 award of this prize (£50) has been made to Dr W d'A Maycock for his contributions to the development of blood transfusion

Liverpool University Medical Students Society

The annual dinner for past and present members of this society is to be held at the Adelphi Hotel, Liverpool, on Feb 8, when the guest of honour will be Sir Clement Price Thomas Tickets (25*s*) may be had from the medical dinner secretary, Medical School, University, Liverpool, 3

Eli Lilly Medical Research Fellowship

Applications are invited before April 30 from doctors registered in South Africa for this fellowship for medical research in the United States The value of the fellowship is $250 a month for twelve months, with return travelling expenses Further particulars can be had from Dr H A Shapiro, P O Box 1010, Johannesburg

Society of Chemical Industry

On Wednesday, Jan 25, at 6 30 P M, the third meeting in the series on Nutritional Requirements and Food Fortification will be held at Burlington House, Piccadilly, London, W 1 The speakers will be Miss E M Widdowson, D SC, and Miss D L Hollingsworth, and the subject will be Calcium and Iron

Salon des Médecins

An art exhibition for doctors, dentists, pharmacists, and veterinary surgeons will be held from March 4 to 25 at the Musée d'Art Moderne, Paris British doctors are invited to send details of name, address, qualifications, and titles of exhibits to Dr Malet, 67, Avenue Pierre Larousse, Malakoff (Seine), France, without delay Exhibits should bear the same information and should be sent to Messrs Davies Turner, Ltd, 47, Graham Terrace, London, S W 1, and not direct to Paris

---

A newspaper report on the use of 2 phenyl 3 methyl tetra hydro 1, 4 oxazine hydrochloride as a slimming pill says that the medical advisers of the firm (Messrs Pfizer) which has introduced it are satisfied that it is "safe enough to be sold over the chemists counter" Dr R K Phillips informs us that "the advice of myself and of my medical colleagues and that of the firm has always been that the drug should be taken only under medical supervision"

Directory of Convalescent Homes—King Edward's Hospital Fund have published the 1956 edition of their directory of homes serving Greater London Copies may be had from the Fund, 10, Old Jewry, E C 2 (7*s* 6*d* post free)

ECLAMPSIA

Sir,—I would like to answer Dr Salzmann (Jan 7) y referring him to an account, just published, by rofessor Lambillon, concerning his experience with oxæmia and eclampsia in the Belgian Congo [1]

While visiting the U S A Professor Lambillon was struck y the high frequency (10%) of severe toxæmia among the oloured women everywhere in the southern States These ere getting the same antenatal care as their white sisters n the North, among whom eclampsia is very rare but latent re eclampsia (according to Professor Lambillon) is still very ommon although their diet is high in protein

In the Belgian Congo until twenty years ago eclampsia as unknown among natives, but nowadays the frequency f this disease is rising in towns, where people from the ural districts are getting plenty of European food, to which heir constitution must adapt itself Even now there is a istrict, with a population of two million, where not a single ase of toxæmia has ever occurred, here, according to radition, pregnant women drink only water, their diet is egarded by Professor Lambillon as inadequate, yet it eems to suit expectant mothers better than the adequate European diet

The *ratio of boys to girls* born in the Belgian Congo s the same as elsewhere in the world

Amsterdam

R Schuurmans

FOOD-POISONING

Sir,—Your editorial last week will be widely welcomed by most medical officers of health, and, representing the medical practitioner's viewpoint, must command attention

I am a little disappointed that you did not stress two factors which contribute to the over-large figure of 39% of all incidents reported as "cause unknown"

As a medical officer of health of a borough many of whose residents spend their working day in the city and partake there of midday meals in hotels, cafés, and restaurants, I find many incidents which cannot be investigated This must be the experience of other medical officers in the Home Counties and outside other great towns

Another factor is that, in this antibiotic age, many patients have recovered before notifications are forwarded to the local medical officer Sometimes the notifications are sent in with the monthly accounts Investigations at this stage are, of course, quite useless, and the medical officer must feel unhappy at the loss of so much opportunity of adding to his local knowledge of the essential causes of food-poisoning

I do not think that legislation has run ahead of public opinion I was recently approached by the secretary of a local women's citizens association to take action with regard to the sale, on open fish counters, of certain food which would not be cooked, and in many other instances public opinion is rebelling against careless practice No one can incriminate cigarette ash, though cigarette ends in bread are rather revolting, but surely let us first get the hygiene right and then tackle the bigger question of the unknown "virus"

I quite agree with on-the spot investigation by the medical officer of health, provided he has the assistance of a team with local knowledge, and a "free" hand to investigate

L R L Edwards

HORMONAL EFFECTS OF CHLORPROMAZINE

Sir,—Treatment of 200 psychiatric cases with chlorpromazine ('Largactil') has shown us that this drug produces far reaching endocrine changes, commonly including galactorrhœa,[1] which are apparently due to transient partial impairment of the hypothalamus We describe here the effect of chlorpromazine on secretion of anterior-pituitary tropins in man and animals

Method

Chlorpromazine was administered to the patients thrice daily in doses ranging from 25 to 100 mg, together with vitamins of the B complex

Chlorpromazine was administered subcutaneously to 35 rats at a dosage level of 10 mg per kg body-weight, and to 20 rabbits at a dosage level of 1 mg per kg

Results

Follicle stimulating Hormone (F S H) and Luteinising Hormone (L H)

One patient, a 16 year old girl with a long standing psychic disorder, probably schizophrenic, had increased gonadotropin values before treatment was started These values increased, together with those for œstrone, at the fifteenth to twenty-fifth day of treatment (see accompanying table) Another patient, a male who was a borderline case of schizophrenia, before treatment excreted F,S H 100 rat units (R U) per litre of urine and no L H On the eleventh day of treatment the values went up to F S H 200 R U per litre and L H 100 R U per litre This increased hormone production was maintained for another fourteen days

URINARY EXCRETION OF HORMONES, BEFORE AND DURING TREATMENT WITH CHLORPROMAZINE, IN A 16 YEAR OLD GIRL

Day of treatment	F S H (R U per litre)	L H (R U per litre)	Œstrone (I U per litre)
Before	200	100	10
1st–14th	200	100	10
15th–25th	1000	500	50
26th–36th	200	100	10

In 15 mature female rats vaginal smears were examined daily In 10 there were typical and regular patterns of the sexual cycle, averaging one day œstrus followed by four day anœstrus After this cycle was clearly established, subcutaneous injections of chlorpromazine were started From that day onwards the pattern of the cycle changed to five day œstrus followed by five day anœstrus This periodicity prevailed even in animals which had shown an irregular pattern of cycle before treatment was started When injections were discontinued after 8 weeks, the former pattern of cycle gradually returned in all the rats Intraperitoneal injections of chlorpromazine produced permanent anœstrus

Prolactin

25 female patients were daily examined for production of colostrum or milk Before chlorpromazine treatment no colostrum could be obtained from their nipples Within two weeks after treatment was begun, 17 showed colostrum on pressure or even pronounced galactorrhœa The remainder produced colostrum for a short period, lasting three to seven days, 6 had only unilateral secretion of colostrum

10 immature female rabbits, after being primed with œstrogen, received subcutaneous progesterone 0 5 mg daily, together with chlorpromazine 10 mg per kg body weight After time intervals varying from 17 to 34 days they were killed and the generative phase of the uterus was determined microscopically Whereas in control animals the second phase disappeared spontaneously after seventeen days of continued progesterone injections, the second phase was maintained in rabbits which had chlorpromazine added to the progesterone So far we have been able to keep up the second phase for thirty-four days, which may indicate endogenous production of prolactin The mechanism of this effect is being studied

Corticotrophin

4 patients were checked daily for urinary 17 ketosteroid output in the urine Before treatment 3 female patients had

blood-pressure accurately in patients with aortic-valve disease, and the pulse-pressure, which averaged 27 mm Hg (109/82), is apparently not always a reliable measure of the degree of aortic stenosis The second heart sound was normal in 5, diminished in 9, and not heard in 2 cases on auscultation in the aortic area, though probably it could have been found by phonocardiography we do not think it is a helpful sign in the diagnosis or in the assessment of the severity of aortic stenosis

The heart was little if at all enlarged, the cardiothoracic ratio averaging 51 5% and being between 47% and 55% in all but cases 7, 9, and 11 Large hearts were uncommon, mainly because there were no patients with much aortic incompetence, but this did not exclude concentric hypertrophy of the left ventricle, which was found in the patients who died Some prominence of the left ventricle was seen on radioscopy, even in the smaller hearts, and there was some prominence of the first part of the aorta in most of the cases with congenital lesions Calcification of the aortic valves was seen in all the patients except the 2 children

The electrocardiogram always showed severe left-ventricular strain and deep T wave inversion in leads I, V5, and V6, and often in leads II and V4 as well, except in case 7 in which there was right bundle branch block

It was the symptoms that decided us to advise surgery in these 16 patients 11 had syncopal attacks and 5 had them very frequently, 13 had anginal pain and this was often the main reason for their incapacity All had dyspnœa and several had cardiac asthma, showing that the left ventricle was failing, and 2 developed congestive failure after the decision to operate but before their admission to hospital The time between the onset of significant symptoms and operation was not very long, and in those cases where there was delay it was generally a rapid increase of symptoms that led us to advise operation

Results of Operation

All these patients were operated on by Sir Russell Brock, to whom we should like to express our thanks Before discussing the results, the first patient will be described Although he died two years after operation, the amount he could do during these two years showed that he had derived much benefit

Case 1 —When he was 27 he fainted and was told he had a heart murmur He had no symptoms except a tendency to faint, and he carried on a busy general practice When he was 59 he became increasingly dyspnœic, with burning mid sternal pain on even slight exertion, soon followed by loss of consciousness unless he stopped at once Aortic stenosis was diagnosed

His work was proving impossible, so, after two years, aortic valvotomy was performed He resumed his practice without any more attacks of loss of consciousness, but six months later, on a fishing holiday in Scotland, he had some cardiac asthma He continued his practice for another year, but there were increasing episodes of cardiac asthma and finally congestive failure, and he died two years after operation

At necropsy there was much concentric hypertrophy of the left ventricle The aortic valve was bicuspid with severe calcification, and the opposed, rigid cusps were almost closed The other valves were normal, and there was only slight atheroma of the coronary arteries

GOOD RESULTS

Good results were achieved in 5 of the 16 patients—a boy with congenital stenosis (case 11), and 4 adults All have been followed for a year or more

The systolic and diastolic pressures on each side of the aortic valve before and after operation are recorded in table II Fleming (personal communication) has pointed out, however, that the fall in the mean systolic gradient after valvotomy is generally much less than the fall in the peak systolic gradient

In those cases with good results the pressure gradient was greatly reduced after operation—in 3 cases it fell to about half of what it was before and in 2 cases (9 and 11) it was almost abolished Only 1 of these (case 9) developed significant aortic regurgitation In 2 the electrocardiogram was improved, and in 1 the heart became smaller 1 patient (case 8), however, has died from her cardiac condition, and another (case 7) from carcinoma of the bronchus

TABLE II—PRESSURE GRADIENT ACROSS THE AORTIC VALVE BEFORE AND AFTER OPERATION

Case no	Blood pressure before valvotomy (mm Hg)				Blood pressure after valvotomy (mm Hg)			
	Clinical	In left ventricle	In aorta	Systolic gradient	Systolic gradient	In left ventricle	In aorta	Clinical
1	105/80				70	130/?	60/?	120/80*

15	96/74	175/15	53/42	122	14	72/9	58/32	Died
16	115/85	145/9	51/37	94	60	145/17	85/57	

* Died one or two years later † Died some months later

Case 7 —At the age of 38 this man became breathless and within a year he had gross congestive failure After months in hospital this was eventually controlled with thiouracil, digitalis, and mersalyl, but he easily slipped back into congestive failure At 46 he had a large heart, right bundle branch block, severe aortic stenosis without incompetence, but no mitral stenosis

At aortic valvotomy, the pressure gradient was reduced from 70 to 40 mm Hg He returned to work, which he had not been able to do for years A year after operation his condition was excellent and his heart was smaller with a cardiothoracic ratio of 58% compared with 66% before operation He then developed fresh symptoms and a lump appeared on his chest wall On biopsy this proved to be an undifferentiated carcinoma, and necropsy confirmed the cause of death as carcinoma of the bronchus

Case 8 —A woman, aged 40, had had few symptoms until two years previously, although she knew she had a rheumatic heart She had then become dyspnœic and had anginal pain on exertion, she had lost consciousness a dozen times and would have done so more often if she had not been careful to stop at the first hint of pain Finally she could walk no more than 200 yards There was an aortic diastolic murmur and slight mitral stenosis as well as aortic stenosis Her attacks of unconsciousness showed the urgent need for aortic valvotomy, but her aortic incompetence and high pulse pressure (120/70 mm Hg) were against it

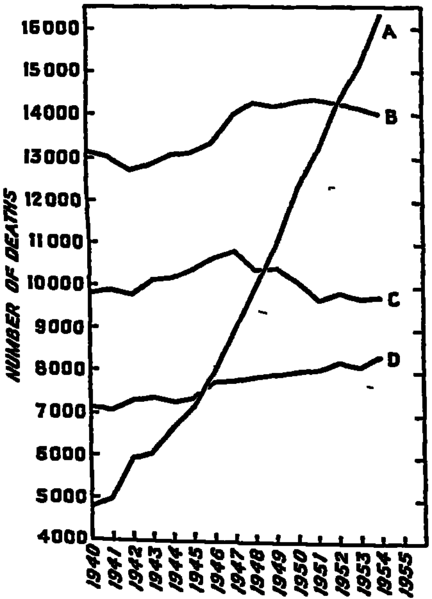
At operation the aortic valve was found to be fibrocalcareous but could be split readily, the pressure gradient across it was reduced from 110 to 55 mm Hg, the mitral valve, which was slightly narrowed (1 0 × 1 25 cm), was divided A year later she was leading a normal life, she was able to walk 2 miles and never felt faint, although she did all the household tasks, such as shaking rugs and polishing, that gave her attacks before There was no increase in the aortic incompetence or in the size of the heart The T waves were biphasic instead of deeply inverted in leads V4, V5, and V6, and upright instead of biphasic in V3 She remained well for another six months but then died suddenly While walking with her husband she had severe sternal pain, and she was only able to utter a few words before she became unconscious and died within five minutes

Case 9 —A woman, aged 48, had been incapacitated with angina for eight years and had had syncopal attacks and cardiac asthma for two years After aortic valvotomy, the pressure gradient across the aortic valve was reduced from 142 to 20 mm Hg She has less dyspnœa and angina, and

THE EPIDEMIOLOGY OF LUNG CANCER IN NEW ZEALAND

SIR,—The title of this article (Jan 7) caused pleasurable anticipation, for it is essential that information lating to the ætiology of carcinoma of the bronchus hall be available from all possible sources However, leasure ebbed away when reading revealed that Dr astcott has failed to note the scientific evidence from many parts of the world that there is a causal relationship etween the number of cigarettes smoked and the ncidence of this disease

The mere setting out of the yearly consumption of obacco, without relating this to the methods of smoking, eglects the most important change in our habit during he past fifty years It is probable that we in this country ed the world in the number of cigarettes smoked per ead of population until 1925 Certainly we were far head of the United States until then Between 1910 and 925 there was an increase of 100% in cigarette con umption in this country The deaths from carcinoma of the bronchus that clinicians have seen in the past five years occurred mainly in men who commenced smoking in the 1914–18 war Smoking habits are acquired before he age of 30 and seldom change in an individual after this This factor merited investigation in New Zealand



Deaths from cancer of lung and bronchus (A) stomach (B) intestine (C), and heart (D) England and Wales 1940–54

We are faced with a very serious epidemic of lung cancer here, as the accompanying figure shows This contrasts the deaths with those from cancer in other common sites I know of no scientific publications which have shown any change of urbanisation sufficient to explain this alarming rise It is explicable on the vast increase of cigarette consumption, and herein lies hope of dealing with the epidemic Articles purporting to be scientific but which fail to analyse this aspect do a great disservice to those who have shed light on this problem by patient research The peak of the epidemic is not in sight, but its height can surely be diminished if we will act on the ascertained facts and ensure that the public is informed constantly of the risks of cigarette smoking The Government is not prepared to do this yet, but surely, Sir, we can expect informed medical writing not to neglect it

ATMOSPHERIC POLLUTION

SIR,—Your article of Jan 7 on the Investigation of Atmospheric Pollution makes one ask whether industrial smoke and the smoke from domestic coal fires is really all there is to the heavy pollution and contamination of the air we breathe Has the time not come for directing our attention also to other common sources of air pollution? Outdoors it is the ever-increasing admixture of exhaust fumes from motor vehicles, particularly from Diesel oil driven vans and buses which deserves close study and efficient action Is it really beyond the wit of engineers and chemists to devise decontaminators, fitted to the exhaust pipes, which would absorb or render harmless the hydrocarbons and the carbon monoxide and possibly other poisonous constituents of these dangerous gases? In the meantime it might not be a bad idea if motorists waiting in traffic queues were compelled to switch off their engines which throw out unmeasured quantities of highly toxic exhaust fumes

Turning now to air contamination indoors, may I make a plea for air sampling and for research into the tobacco smoke pollution of the air we are compelled to inhale in buses, in picture and concert halls, in pubs, and wherever else people meet? It could perhaps be argued that smoke abatement (not unlike charity) should begin at home Whatever good is being done by the creation of smokeless zones and by wider application of technological knowledge to the reduction of coal smoke from factories and from home fires, much of it, I feel, is undone by the perpetual and *still* increasing air contamination with tobacco smoke

Apart from its irritating effect on the mucous membranes and on the air passages of both smokers and passive non smokers and its provocation of coughing, which naturally increases the bacterial content of the atmosphere in closed rooms, the burning of cigarettes and pipes takes up a considerable amount of oxygen from the air we are left to breathe Air-sampling and analysis of the O_2, CO_2, and CO content of the atmosphere in smoky rooms and public vehicles would, I believe, reveal a state of affairs that might shock the guardians of our public health

E G W HOFFSTAEDT

MALIGNANT DISEASE OF THE RESPIRATORY SYSTEM

SIR,—In a statistical survey of this subject[1] I compared the death-rates below age 70 from (*a*) all diseases of the respiratory system except cancer, and (*b*) cancer of the respiratory system, and suggested that possibly the considerable increase in the death rate from lung cancer in the period under review had resulted partly from better treatment of other lung diseases as manifested by the substantial reduction in the death rate therefrom during the same period

It has been suggested that a split-up of these death-rates at the age of 50 could be of interest since it requires some 20–30 years of cigarette smoking to produce lung cancer, and thus if there is any statistical correlation between the two it will be apparent only in death-rates after the age of 50

DEATHS PER 100,000 MALE POPULATION OF ENGLAND AND WALES FROM DISEASES OF RESPIRATORY SYSTEM

Diseases	1932	1938	1948	1949	1950	1951	1952	1953
All except cancer								
Ages 50–70	419 7	360 2	412 3	470 2	403 1	530 2	377 3	404 4
Ages below 50	171 9	127 5	82 4	76 0	57 0	54 2	40 8	30 8
Cancer								
Ages 50–70	48 8	77 8	154 2	162 5	178 7	193 4	203 7	213 2
Ages below 50	3 3	5 6	10 4	10 3	10 4	10 5	10 4	10 3

The death-rates for males up to age 50 and from 50 to 70 are set out in the accompanying table The results are quite remarkable and appear to establish a definite correlation between lung cancer and the tobacco habit This conclusion is of course supported by the fact that during the period reviewed there has been no incompetence The following data suggest that the greater the relief of the stenosis the greater is the risk of producing incompetence

---

[1] Bradshaw, F L *Lancet*, 1955, i 861

In the 5 good results, the pressure gradient was reduced to 40, 55, and 59 mm Hg in the 3 cases where aortic incompetence was not produced or increased, and to 20 and 12 mm Hg in the 2 where it was produced (cases 9 and 11) though in case 11 (where there was congenital stenosis without calcification) it was only slight In the patients who were improved the pressure gradient was reduced only to an average of 75 mm Hg, but even in these cases aortic incompetence was produced in 2 and it was thought to be one reason why the patients were not much better Of the 6 who died, 3 died at once, in the other 3 the pressure gradient was reduced to between 14 and 31 mm Hg, but all developed free aortic incompetence, and this was probably the main cause of their deaths

This risk is increased when the valve is calcified, as it was in all our adult patients Except for young children with congenital or rheumatic disease, it seems unlikely that many patients will reach a stage of severe obstruction without calcification developing We have seen it as early as 18 and 24 years of age This difficulty will be hard to overcome, and McMillan (1955) finds that it is difficult to produce a satisfactory opening even in a necropsy specimen, which must be easier than in a living heart at operation

Our results, however, show that it is possible to get good results even with a calcified valve, and greater experience in surgical technique or in the selection of patients may overcome this obstacle

For example, a patient seen recently had moderate incompetence, so that much doubt was felt about aortic valvotomy, but, in view of the good result in case 8 and his increasing disability, the operation would probably have been advised if we had not had the results of left atrial puncture The left atrial mean pressure was high (22 mm) Analysis of the records according to the criteria of Gorlin et al (1955) suggested that the aortic stenosis and incompetence were of equal importance, and that the aortic valve area had a minimal size of 0 83 sq cm (Gorlin and Gorlin 1951) We thought, therefore, that any increase in size was likely to do more harm from additional incompetence than good from relief of the stenosis, and valvotomy was not advised We are indebted to Dr P R Fleming for these figures and calculations

Another reason why some of the results are disappointing is that the patients were chosen for operation at a late stage of their disease 9 of our 16 patients had left ventricular failure and 3 of these had progressed to right sided failure as well, and all had electrocardiographic signs of severe left ventricular strain Many had reached an age when independent coronary disease is possible, but we think that generally the signs were due not to this, but to changes in the muscle secondary to the aortic stenosis—changes that may become irreversible if the operation is delayed too long

Though the poor outlook without surgery made the decision to operate easier in most of these cases, it is clear that the best time for operation had passed The approach to the aortic valve through the wall of the left ventricle makes it imperative to operate before the muscle of that chamber is irreversibly damaged When the left ventricle shows signs of failure or pain and syncope denotes severe ischæmia, it may be too late for it to recover, even if its burden is relieved

If when severe symptoms are evident it may be already too late for successful surgery, we need signs that left ventricular failure is imminent, so that surgery can be considered sooner The physical signs that point so clearly to the diagnosis are of no help in prognosis because they are compatible with the patient's full activity for many years An increase in heart size would be a clear warning, but it may come too late Measurement of left ventricular pressure and the gradient across the aortic valve is difficult and not without danger, so that it has not been possible to accumulate evidence to correlate with clinical and electrocardiographic findings, as in pulmonary stenosis

The pattern of left ventricular strain in the electrocardiogram seems likely to be the most helpful sign, but more exact knowledge of its prognostic significance is needed This pattern does not prove that the changes are irreversible, because after pulmonary valvotomy it can often be reversed The fact that patients stand aortic stenosis well for so long may mean, however, that by the time symptoms appear important left ventricular strain has been present so long that the changes in the muscle are often irreversible This would suggest that the first sign of left ventricular strain is an indication for surgical treatment, but we think this far from certain, because in some patients it is already present or has been seen to develop gradually during several years while the patient is free from symptoms

This strain pattern is, however, seen more often in those who already have symptoms Thus of the 40 patients reported by Campbell and Kauntze (1953), 24 showed this pattern 17 of these had symptoms of moderate severity but there were few symptoms in 7, 4 of whom were children aged between 4 and 9, where the absence of symptoms is less decisive In contrast to this, among the 16 patients with no strain pattern, 9 had only slight symptoms, and 7 had none

The most hopeful cases seem to be the young patients with congenital aortic stenosis where the valve is not calcified, but many of these do well without operation, it should, therefore, be advised only when they are losing ground Of 2 such patients in this series, 1 died with free aortic incompetence, but 2 boys, aged 9 and 13 (cases 9 and 11, Campbell and Kauntze 1953), have since had operations with good results

The first had not changed much clinically during five years, but T wave inversion in lead V6 had developed in the electrocardiogram In this case the pressure gradient across the aortic valve was reduced from 72 to 24 mm Hg

The second boy was hardly disabled in 1950 but had lost ground in 1952, he was much the same in 1955 except for increasing left ventricular strain (T wave inversion in V4–V6) Operation was therefore advised and the systolic pressure gradient was reduced from 144 to 13 mm Hg without producing aortic incompetence

Patients with aortic stenosis who have symptoms or a left ventricular strain pattern must be watched closely They should be considered for surgery at the earliest sign of deterioration Some patients do well for a long time after the electrocardiogram has shown signs of left ventricular strain, but these signs in a growing child (Marquis and Logan 1955), or their progression in an older patient when symptoms are getting worse, probably indicate the best time for surgery The chances of success will be better if the valve is not calcified, but even then the risk of producing incompetence cannot be ruled out (case 15)

It is important to emphasise to patients that surgery can improve their prognosis and enable them to lead a fuller life, but that complete restoration of normal valve function and normal activity is unlikely Such complete restoration is what they naturally hope for, and, unless they are warned, they will expect it

Summary and Conclusions

In isolated aortic stenosis, valvotomy is less successful than it is in mitral or pulmonary stenosis

We report the results of aortic valvotomy in 16 patients 6 died and in only 5 were good results achieved Even among these 5, 1 died within eighteen months

The main danger of the operation is the production of aortic incompetence The reason for this is that in adults with advanced disease the aortic valve is calcified and deformed

THE EPIDEMIOLOGY OF LUNG CANCER IN NEW ZEALAND

SIR,—The title of this article (Jan 7) caused pleasurable anticipation, for it is essential that information relating to the ætiology of carcinoma of the bronchus shall be available from all possible sources However, pleasure ebbed away when reading revealed that Dr Eastcott has failed to note the scientific evidence from many parts of the world that there is a causal relationship between the number of cigarettes *smoked* and *the* incidence of this disease

The mere setting out of the yearly consumption of tobacco, without relating this to the methods of smoking, neglects the most important change in our habit during the past fifty years It is probable that we in this country led the world in the number of cigarettes smoked per head of population until 1925 Certainly we were far ahead of the United States until then Between 1910 and 1925 there was an increase of 100% in cigarette consumption in this country The deaths from carcinoma of the bronchus that clinicians have seen in the past five years occurred mainly in men who commenced smoking in the 1914–18 war Smoking habits are acquired before the age of 30 and seldom change in an individual after this This factor merited investigation in New Zealand

MALIGNANT DISEASE OF THE RESPIRATORY SYSTEM

SIR,—In a statistical survey of this subject[1] I compared the death-rates below age 70 from (*a*) all diseases of the respiratory system except cancer, and (*b*) cancer of the respiratory system, and suggested that possibly the considerable increase in the death-rate from lung cancer in the period under review had resulted partly from better treatment of other lung diseases as manifested by the substantial reduction in the death-rate therefrom during the same period

It has been suggested that a split-up of these death-rates at the age of 50 could be of interest since it requires some 20–30 years of cigarette smoking to produce lung cancer, and thus if there is any statistical correlation between the two it will be apparent only in death-rates after the age of 50

DEATHS PER 100,000 MALE POPULATION OF ENGLAND AND WALES FROM DISEASES OF RESPIRATORY SYSTEM

Diseases	1932	1938	1948	1949	1950	1951	1952	1953
All except cancer								
Ages 50–70	419 7	360 2	412 3	470 2	403 1	530 2	377 3	404 4
Ages below 50	171 9	127 5	82 4	76 0	57 0	54 2	40 8	30 8
Cancer								
Ages 50–70	48 8	77 8	154 2	162 5	178 7	193 4	203 7	213 2
Ages below 50	3 3	5 6	10 4	10 3	10 4	10 5	10 4	10 3

The death rates for males up to age 50 and from 50 to 70 are set out in the accompanying table The results are quite remarkable and appear to establish a definite correlation between lung cancer and the tobacco habit This conclusion is of course supported by the fact that during the period reviewed there has been no swallow pus, the course of breast-feeding was not altered by superficial mastitis

---

[1] Bradshaw F L *Lancet*, 1955, i, 861

The infecting organism in every instance examined was *Staphylococcus pyogenes* The in vivo sensitivity of the staphylococcus to antibiotics did not necessarily tally with its in-vitro sensitivity Although the resistance of superficial mastitis to penicillin therapy may have been due to the fact that the mother derived her staphylococci from the resistant strains commonly inhabiting hospitals, penicillin 1,000,000 units daily seemed to be less effective than would be expected on that score alone

There was a firm association with concurrent infection Of the 24 cases of superficial mastitis, either alone or preceding intramammary mastitis, in 14 infection which was, or may be presumed to have been, staphylococcal, was present either in the mother or in her baby or her husband, and in the 25th case an intramammary abscess had been incised Thus 60% may be said to have had concomitant staphylococcal infection (table I) Manual expression of colostrum after delivery appeared to have increased the incidence of this kind of mastitis, although it was not much practised in the wards 13 of the patients had used it

Treatment

Prevention evidently consists in avoiding infection of the skin of the areola, which is very vulnerable to trauma and chemical irritants Antiseptic applications have been avoided so far as possible, but, since the strong association with concurrent infection has been recognised, mothers who have pustules or whose babies have paronychia or staphylococcal conjunctivitis are recommended to use a bactericidal soap when washing their trunk The use of penicillin cream on the nipple or a spot seems quite unjustifiable Likely causes of pustules on the breast are also avoided where possible rubber linings to brassières are discouraged, and adhesive plaster is not used in dressing an abscess for fear of causing another Treatment usually consisted in giving an antibiotic and opening the abscess

Since several of these patients had already been treated elsewhere, the numbers allocated early enough to different forms of treatment are too small to show their relative merits Table II gives the numbers receiving each treatment and shows how many resolved and how long the unresolved took to reach the stage of incision or spontaneous discharge Of the 12 abscesses treated initially with penicillin only 1 resolved The 11 others seemed to take longer than usual to ripen for incision, and, since incision was in the end inescapable, the penicillin was of doubtful service The initial use of either aureomycin or chloramphenicol apparently cured the mastitis in 3 of 6 cases

Our present practice is that, if the lesion is still scarcely larger than a lentil when first seen, aureomycin 250 mg six-hourly is given The effectiveness of this treatment is visible within forty eight hours Where it is ineffective, or where the induration is already as large as a pea, antibiotics are considered less necessary, unless the infection appears to be exceptionally virulent, since evacuation of pus is sure to be necessary ultimately and has to be undertaken as soon as it is physically possible

TABLE I—CONCURRENT INFECTION ASSOCIATED WITH SUPERFICIAL MASTITIS

Type of mastitis	Superficial only	Intramammary only	Superficial succeeded by intramammary	Intramammary succeeded by superficial
Number of cases	20	104	4	1
Site of associated infection				
Baby				
Skin	3	4	1	
Conjunctiva	3	5		1
Abscess	0	1		
Mother				
Skin	5	2	1	
Conjunctivitis	0	1		
Vulval abscess	0	1		
Urine (staph)	0	1		
Father				
Barber's itch	1	0		
Total *no* of cases with infection	12 (60%)	15 (14%)	2	1

TABLE II—RESULTS OF ANTIBIOTIC TREATMENT OF SUPERFICIAL MASTITIS

Antibiotic	No of cases	No resolved without opening	Duration of mastitis before opening (days)
None	5	0	2–6
Penicillin alone	8	1	6–21
Aureomycin 1 g daily	4	2	1–4
Chloramphenicol 1 g daily	2	1	27
Penicillin followed by aureomycin	4	0	2–9
Unknown	2		
Total	25	4	

A stab incision under brief general anæsthesia and preservation of the cavity walls by refraining from using sinus forceps to open the cavity will, if undertaken early enough, enable the mother to continue breast-feeding, unless the incision is very close to the nipple The incision is best made at the margin of the areola It is of course absolutely essential for the breast to be emptied as often and as well as it had been before If emptying is impracticable, suppression of lactation must be started in good time to avoid unnecessary suffering and to prevent superimposed intramammary mastitis

INTRAMAMMARY MASTITIS

Intramammary mastitis is characterised by pain in the breast, a lump in the glandular tissue, a flush of the skin over the affected area, pyrexia, and reduction of secretion from the affected breast The most constant and important of these symptoms and signs is the lump Although a lump may be present in a lactating breast without amounting to mastitis, the other symptoms and signs have not been seen where there was no palpable lump in any case in this series or in the many other cases seen In the present 109 patients the criterion of mastitis was therefore taken to be the presence of at least one other symptom or sign besides the lump All 109 patients had pain, and 71 had pyrexia On this basis of diagnosis no difference could be drawn, in the early stages of intramammary mastitis, between the condition of the mother with intense engorgement and pyrexia which resolved entirely on emptying the breast and the case where resolution by emptying was not obtained and an abscess resulted

This preliminary stage, when intramammary mastitis is manifest yet resolvable, presents features which are hard to reconcile with the usual view of intramammary mastitis The assumption was often made in the past that the condition of the breast and the pyrexia were due in the first place to bacterial invasion, but Romanis and Mitchiner (1952) comment that engorgement of the breast may be regarded as the first stage in intramammary mastitis

In the present series 77 patients (71%) recovered completely without detectable residual induration, and a further 10 did not require incision (fig 1) Since most of the patients were given antibiotics, the defeat of the bacteria may have caused healing and restoration of the normal tissues of the breast, but antibiotics were not essential for this, because 4 patients had thirteen pyrexial attacks with retention which resolved entirely on emptying the breasts at home without other treatment. Recovery like this was often seen before the advent of antibiotics, as Isbister (1952) has remarked occurred during a period of two years, the material consisting, in fact, of 30,000 card groupings Of the 5 errors, 2 occurred because the cards at that time were not protected against moisture, and accordingly the reagents on some cards had been completely spoiled during a damp summer month Since then every card has been packed in a moisture proof envelope with control paper enclosed for an easy check on the effectiveness of the protection The other errors were due to grave disregard of the directions for use

Finally I should like to point out that the groupings in this material were carried out by a rather large number of doctors and technicians in various hospitals Thus, the results should not be directly compared with those published for other new methods, which usually relate to the worker's own laboratory only

WERTHEIM'S HYSTERECTOMY

SIR,—I read with interest Mr Mills's account last week of his modified procedure based on the Howkins combined abdomino vaginal hysterectomy, as I have been using an exactly similar method for the last three years During that time I have treated in this way about fifteen cases of carcinoma of the cervix, though not, as yet, any of carcinoma of the body of the uterus

Mr Mills's statements as to the increased facility of isolation and division of the parametrium can be fully substantiated, while the use of a pack at the conclusion of the vaginal part of the operation, by raising the contents of the pelvis higher up into the abdomen, makes the abdominal part of the operation quicker and easier The reduced time spent in the Trendelenburg position is of value both to the patient and to the anæsthetist While the numbers are too small to be of statistical significance, the impression is that the incidence of ureteric fistula is diminished, though just why this should be so is not apparent

The chief disadvantage of the method is the necessity of being certain that the growth is operable, and it has been thought advisable, on one or two occasions, to open the abdomen before proceeding to the vaginal part of the operation

"INFECTIOUS ROSEOLA"

SIR,—Dr Fletcher describes in his letter (Jan 7) a small epidemic of "infectious roseola" in Palestine The disease he describes is well known to those with tropical experience as dengue fever, spread by aedes species In the former Netherlands East Indies the more popular name was *vyfdaagsche* or *van der Scheersche koorts* (five day fever or van der Scheer's disease)

The incubation period is generally 5–8 days with extremes of 3–10 days Acute onset, with muscle pains, pyrexia up to 104°F, pain on turning the eyes, slight conjunctivitis, and initial exanthema and enanthema, is common The exanthema may differ from case to case, but usually one can see against the background of large livid maculæ after 3–6 days small, dense, vivid red, spots or papulæ beginning on the chest, waistline, hands, feet, and arms, the face is generally spared Occasionally petechiæ are seen in the spots After defervescence the exanthema disappears, often with fine desquamation General lymphadenopathy is common, the spleen is not enlarged The tongue is coated, anorexia, nausea, and vomiting are common On lumbar puncture the cerebrospinal fluid is under high pressure, and contains an excess of albumin, glucose, and white blood cells A distinct leucopenia is valuable corroborative evidence In the well known Greek epidemic the mortality rate was 0 03%, but usually dengue fever is a benign, though temporarily incapacitating, disorder It has nothing to do with roseola infantum (Zahorsky) The virus of dengue, discovered by Ashburn and Craig, may be transferred to man and animals by injection of the patient's blood in the first days of fever The virus has not been cultivated from human blood, but by repeated passage in infected mice it can be grown There are several strains of dengue virus The infection does not confer immunity

Hilversum, Holland D P R KEIZER

"OEDÈME BLEU"

SIR,—Dr I Macalpine and Sir James Paterson Ross in their paper last week describe a syndrome better known to a past than to the present generation of neurologists They define it as "a not uncommon form of 'hysterical' affection of joints simulating medical or surgical disease"

The neurologist will find it hard to know what this means, and will ask why the joints have been chosen by the authors as the primary and essential seat of the condition they have described anew He will ask also, what is the meaning of an hysterical affection of a joint, for the disturbance in hysteria is primarily one of activity and not one of structure, while the joint is a passive mechanism under the control of muscles Surely, in the scientific sense there cannot be an hysterical affection of a joint, though there might be of the muscular control of a limb's movement at a joint

Now hysterical paralyses of hand or foot (and this implies paralyses of muscles of forearm or of leg, as well as of muscles in hand or foot) are not usually or typically accompanied by the striking condition named blue œdema, as first described by nineteenth century writers and now again brought to notice by the present authors Blue œdema is a sequel only to immobility of hand or of foot due to sustained muscular spasm and the fixation it produces, the spasm being psychologically determined In other words, it is a sequel to what the older writers called contracture (not distinguishing between active muscular spasm and fibrous changes in muscle leading to its shortening and loss of contractility)

Volume 128 of the New Sydenham Society's publications, which includes some of Charcot's clinical lectures on nervous diseases, contains the description of many such cases, which Charcot explicitly differentiated from organic paralysis and fraudulently produced states Charcot also pointed out that the fixating spasm may disappear under chloroform anæsthesia, yet ultimately secondary tissue changes do occur so that even under anæsthesia a full range of passive mobility may not be possible

In short, "blue œdema" is a syndrome in which the primary and the sole psychogenic factor is muscular spasm leading to fixation of joints Secondary tissue reactions, which are not psychologically determined, are œdema, cyanosis, and changes in joints and peripheral circulation

To label the entire syndrome as the expression of an hysterical affection of joints is wholly to misunderstand its origin and complex nature

I say no more of the authors' inadequate references to the writings of Charcot and Babinski than that Charcot did not include hemiplegia and fraud under the heading of *grande hysterie* In the Sydenham volume which I have cited, he explicitly differentiates muscular spasm, or "contracture," from organic hemiplegia and fraudulently produced states To suggest that Charcot did not know the differences between these disparate states is not possible for any serious student of his writings

London W 1 F M R WALSHE

SIR,—One feels indebted to Dr Macalpine and Sir James Paterson Ross for their article, which was not only interesting but also very stimulating for further consideration of the "hysterias" However, there are, I think, several points that are open to debate

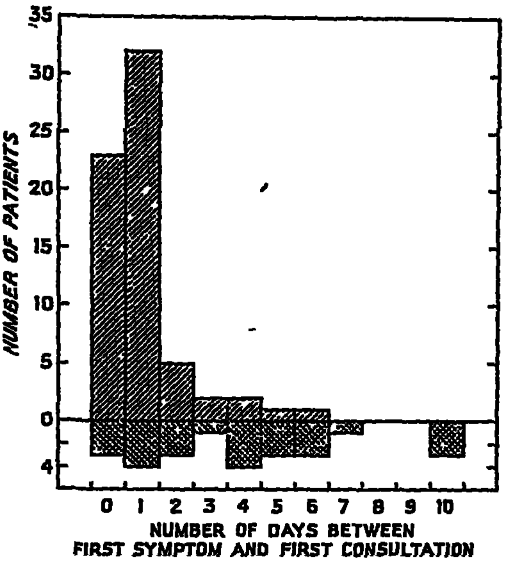

Fig 2—Importance of early treatment of intramammary mastitis *above line* complete resolution, *below line*, residual lump or scar from incision

else to have had a recurring cause—*e g*, temperamental babies—since between them they had forty-four attacks

Probably many women have transitory attacks—complete with pain, lump, and pyrexia—repeatedly during lactation Where the mother thinks little of the signs in her breast, the condition can easily be mistaken for influenza Mastitis should always be suspected when influenza is diagnosed in a woman who is, or who has been recently, lactating

Analysis of the incidence of mastitis shows that there was a preponderance of primiparity and of girl babies, which fact suggests that these factors may have contributed to the failure of emptying Primiparæ, whose breasts offer greater difficulty in suckling (Gunther 1955a), were in the ratio of 76 to 31 multiparæ, whereas the intake of the hospital was 1651 primiparæ to 1054 multiparæ ($\chi^2 = 4\ 67$, $p < 0\ 05$) Dean (1951) has shown that, in the first days of life, girls take less milk than boys do There were more girls than boys among the children of those who developed mastitis in the first ten days 20 girls to 10 boys ($\chi^2 = 3\ 99$, $p < 0\ 05$) But in the children of all the mothers who got mastitis there were only slightly more girls (55 girls to 50 boys from among 1247 girls and 1308 boys born) In an earlier investigation the mothers of small babies were found to be particularly at risk, but in this series that was not so, perhaps because the risk was known

Treatment

The most important part of treatment, as Walsh (1949) pointed out, is to begin early (fig 2) If infection comes, the organism will be *Staph pyogenes*, and antibiotic therapy, not sulphonamides, should be given for prevention Since the mastitis is due in the first place to failure of emptying, emptying must be maintained during treatment and while œstrogens take effect, if suppression is decided on The urgency of treatment depends not only on the threat of infection but also on the finding that the lump is likely to empty its contents in the first day or two of the disease, but that if it has not done so by the third day it is unlikely to do so at all

Since in the present cases and in many others : ill effects followed breast feeding in the first days, t obvious way of dealing with the secretion of m in the first two days was taken where the mother w willing to continue In a few cases the pain of feeding w too great, and, since this was worst when the draug reflex was strongly induced, the humalactor milki machine, which evokes a weaker reflex, was found to wi draw new secretion less painfully than the baby coul and by virtue of its being able to act for fifteen to twen minutes on a breast without causing trauma it wou sometimes withdraw the pent up secretion where the ba would lose interest in five minutes and fail in the job

It was found that, where the lump was not diminish by the third day, an abscess was likely to be formed, a then resolution would usually take place only if lactati was suppressed It seemed better to suppress lactati as soon as quick resolution became improbable In t way slow but complete resolution, a cold abscess, or worst a small abscess is likely to be the outcome In t series 3 patients had had penicillin for some days befo they came to us with a deteriorating mastitis, but who lactation had not been suppressed, and only in them d we see the extensive destruction of breast tissue, t copious pus, and the ugly scarring which is the terror mastitis The deleterious effects on mastitis of sucklin once infection has set in, may be partly due to t spread of infection by the pumping action of the draug reflex within the breast (Gunther 1955b)

The end-result may also be poorer if secretion is allow to persist until the time of incision, because fresh are of retention are then hard to avoid on the day aft incision Fig 3 shows the relation of the final outcom in cases where lactation was suppressed and antibioti were used, to the times when suppression and antibioti were started The interrupted line in the figure encircl the entries relating to patients where emptying was al done It will be seen that neither suppression of lactatio even if it precedes mastitis, nor antibiotic therapy give early is as effective as both procedures together wi emptying of the breast

The object of incision is of course to drain the absce with the least residual scarring not only of the skin bu also of the mammary tissue With the proviso that th secretion of milk should already have been largely su pressed, and that drainage is judged to be ultimatel necessary, the sooner the incision is undertaken the bette Much unnecessary destruction of the breast can resul from waiting to be confident of fluctuation, and, whe there is doubt about the presence of pus, the lump shoul be explored with a needle under general anæsthesia an

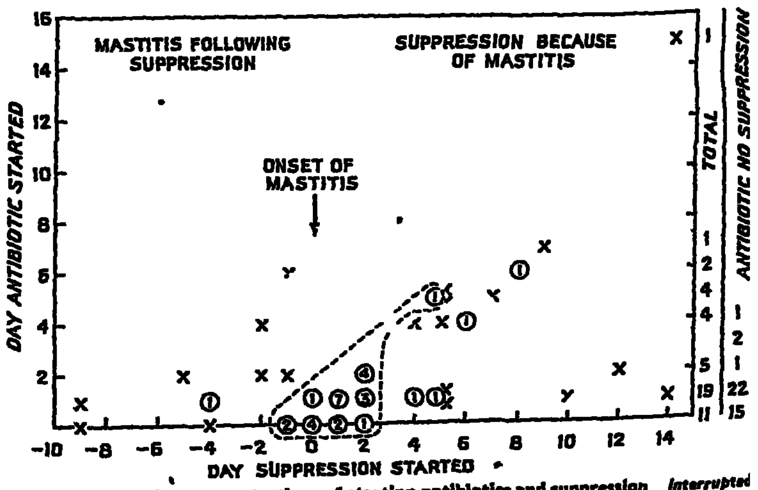

Fig 3—Relation of outcome to time of starting antibiotics and suppression *Interrupted line contains cases in which emptying was achieved*, X subsequently incised *numerals in rings denote number of cases which resolved*

occurred during a period of two years, the material consisting, in fact, of 30 000 card groupings Of the 3 errors 2 occurred because the cards at that time were not protected against moisture, and accordingly the reagents on some cards had been completely spoiled during a damp summer month Since then every card has been packed in a moisture proof envelope with control paper enclosed for an easy check on the effectiveness of the protection The other errors were due to grave disregard of the directions for use

suppression stilbœstrol 5 mg thrice daily for three days, twice daily for three days, and then 1 mg thrice daily for two days, twice daily for two days, and once daily for two days

Summary

129 cases of acute mastitis were studied

Superficial mastitis was found to be associated with other forms of staphylococcal infection and, except for the very early stages, to resist antibiotic treatment

Reasons are put forward for ascribing the lump, pain, flush, and pyrexia of intramammary mastitis to retention of milk and not in the first place to infection At first, pyrexia does not signify pus, pyæmia, or poor prognosis

The outcome depends mostly on the time of starting treatment, which should consist of antibiotic protection, emptying of the breast, and local heat

Prevention is thought to consist in ensuring adequate emptying of the breasts, which can be assisted by antenatal care and by suggested methods of managing lactation until weaning is complete

The pyrexia of early intramammary mastitis is probably due to pyrogens not of bacterial origin

Sites holding stagnant colostrum or milk are commonly infected by *Staph pyogenes*

My thanks go to Mr J. D Martin, my surgical colleague in this work, and to Prof W C W Nixon and the staff of the obstetric hospital, University College Hospital

ACUTE BARBITURATE POISONING

P M G BROUGHTON
B Sc Lond, F R I C

G HIGGINS
B Sc Oxfd

J R P O'BRIEN
M A, B Sc Oxfd

From the Department of Clinical Biochemistry, Radcliffe Infirmary, Oxford

ACUTE barbiturate poisoning has become a serious problem in many countries Several workers have commented on the increasing incidence of such poisoning, and the relatively large number of fatalities (Nilsson 1951, Moore et al 1952) The number of cases admitted to this hospital has increased from 3 in 1945 to 41 in 1954 Once such patients are admitted to hospital their chances of survival are greatly increased, and early diagnosis is probably the most important factor in reducing the number of deaths Biochemical analyses can be of great value in confirming the diagnosis rapidly, assessing the severity of the poisoning, and following its course

In the past, methods for the estimation and identification of barbiturates in biological material have been slow, tedious, and insensitive, and the rôle of the laboratory usually limited to confirming the diagnosis by qualitat tests on urine and gastric contents The introduction ultraviolet spectrophotometric methods (Walker et 1948, Goldbaum 1952) has enabled barbiturates to rapidly and specifically estimated in any material, b since the toxicity of barbiturates differs considerabl quantitative analysis is of limited value unless the dr can be identified (Wright 1954) A spectrophotomet method, by which barbiturates may be estimated a partially identified within an hour (Broughton 1956), n enables results to be available in time to aid in t treatment of patients

TABLE I—CLASSIFICATION OF BARBITURATES

Barbiturate	Proprietary names	Substituents on 55 position	Duration pharmaco gical actio (Martinda 1952)
Phenobarbitone	'Luminal'	Ethyl phenyl	Long
Barbitone	'Veronal' Medinal'	Ethyl ethyl	Long
Butobarbitone	Soneryl'	Ethyl *n* butyl	Intermedi
Amylobarbitone	'Amytal'*	Ethyl iso amyl	Intermedi
Cyclobarbitone	'Phanodorm'	Ethyl cyclohexenyl	Short
Quinalbarbitone	Seconal'*	Allyl 1 methylbutyl	Short
Pentobarbitone	'Nembutal'	Ethyl 1 methylbutyl	Short

* 'Tuinal is a mixture of amytal and seconal and its action "short"

We record here the results of analyses of specimens fro 36 patients, of whom 1 died, who were admitted to th hospital between March, 1952, and August, 1955, a from 10 persons found dead, after the ingestion commonly prescribed barbiturates

Materials and Methods

Most of the living patients in this series were unco scious on admission to hospital, and, with many, b chemical analysis was necessary to establish the dia nosis Samples of blood, urine, and gastric contents we analysed during recovery Necropsy specimens of bloo urine, cerebrospinal fluid (C S F), liver, kidney, a intestinal contents, taken from patients found dea were also examined

Blood-barbiturate levels were determined in 5 cas (nos 4, 5, 13, 14, 17) by the method of Walker *et a* (1948), and in the remainder by a modification (Broughto 1956) of Goldbaum's (1952) method The barbiturat ingested are listed in table I These were identified fro the patient's history, by measurement of the amount alkaline hydrolysis under standard conditions (Broughto 1956), or by the methods described by Turfitt (1948 Barbiturates may be prescribed as either the acid or th sodium salt, and all levels reported here are of the ac form of the particular *55'* disubstituted barbitura named

The degrees of consciousness of these patients a defined as follows

U=unconscious *does not respond to painful stimuli, suc as strong supra orbital pressure*

S=semiconscious responds to painful stimuli, moving a groaning, but unable to talk

D=drowsy answers simple questions, but falls asleep undisturbed

A=awake rational

Consciousness was said to have returned when th patient regained the ability to answer simple questions

Results

LIVING PATIENTS

The highest blood-barbiturate levels found in patient after their admission to hospital, together with the dos lumbar veins, and so increases the pressure in the spinal theca, irrespective of what may be happening at a higher level One can only presume that cord compression does not occur in Dr Belton's practice since he has always found the effects of jugular compression to be identical with those produced by straining In that case he could well afford to dispense altogether with the Queckenstedt manœuvre, but in the interests of good practical neurology he would be better advised to carry out the full orthodox routine of recording the comparative effects of right, left, and bilateral jugular compression, together with those of coughing and straining

Department of Neurology,
University of Manchester

L A LIVERSEDGE

DEATH OF PATIENT WITH ARTIFICIAL PNEUMOTHORAX

Dr PATRICK O'ROONEY writes "In last week's issue you mention (p 110) the death of a patient with artificial pneumothorax Readers are referred to a report in the *Southend Standard* As I carry out most of the refills in the Southend area, I would be very much obliged if you would allow me to explain that this death did not take place in the Southend area"

Medicine and the Law

Payment for Drugs

THE Worcestershire Executive Council has taken action in the case of a doctor who, it was alleged, failed to collect the shilling prescription charge from patients to whom he dispensed drugs [1] The case is of special interest because it raises questions as to the responsibilities of practitioners in regard to the collection of these charges

The doctor told the council's investigating committee that the drugs in question were free samples which he had received from drug houses, and he did not feel justified in charging for them He did not consider that the stocking of his dispensary with free samples was a satisfactory method, but "it saved a lot of time and they are sometimes easier to give"

He had, he said, a small stock of ordinary medicines, but having dispensed these for patients, he was often presented with the difficulty of changing a £1 note Sometimes the patients offered to bring the charge on the next visit In such circumstances he found it difficult ever to collect the charge He had paid over all the charges he had received

The investigating committee reported that it did not object to the use of free samples but deprecated their use as a source of supply The council decided that the doctor had "abjectly failed" to collect the charges It was agreed that £10—"a reasonably accurate estimate of the amount involved"—should be withheld from his remuneration

The press report does not disclose the circumstances in which the doctor dispensed these drugs, but there are three possibilities

(*a*) The drugs may have been dispensed (under paragraph 7 (9) (a) of the Terms of Service) for immediate application or administration or for use before a supply could be obtained in the ordinary way

(*b*) The doctor may have been acting as a "dispensing doctor" in accordance with arrangements made by the executive council for patients living in a rural area or who have other difficulties in obtaining drugs

(*c*) The drugs may have been supplied by the doctor apart from any obligation under head (*a*) or (*b*)

The liabilities of the patient and the practitioner with regard to the shilling prescription charge vary accordingly If the drug is supplied under either head (*a*) or (*b*), the patient is liable to pay to the doctor the shilling prescription charge (N H S [General Medical and Pharmaceutical] Regulations, 1954, reg 30 [1]) The doctor is under no obligation to supply the drug except upon such payment (reg 30 [2]), alternatively, he may dispense the drug and, if he has difficulty in recovering the charge at a later date, he may sue for it as a civil debt (reg 34) In these circumstances, the patient's liability would appear a purely civil one to the practitioner, the patient is not under any direct obligation, civil or criminal, to the State

The question then arises as to whether the practitioner is under a duty to enforce his right to the shilling Here the position varies

As to head (*a*) in respect of his duty under paragraph 7 (9) (a) of the Terms of Service, every practitioner receives a payment of 2*s* 6*d* per annum for every 100 patients on his list, the automatic receipt of that payment imposes a clear obligation on the practitioner to demand and account for the shilling charge

As to head (*b*) the practitioner may claim payment for drugs supplied either on a flat-rate basis for each patient (with additional payments for especially expensive items) or on the basis of the *Drug Tariff* for every item supplied If the practitioner claims payment on either basis, then clearly he ought to recover the shilling charge, but if he does not claim, there appears to be no obligation upon him to recover the charge and no good reason why the executive council should expect him to do so This view of the matter appears to be confirmed by the statement in the official *Handbook for General Medical Practitioners* (para 74) that the Minister has determined that the payment of a dispensing doctor for the supply of drugs and appliances is subject to the condition that the charges be collected and paid over

In the case of head (*c*) the patient appears to be under no liability to pay the shilling charge, so there can be no question of the practitioner being obliged to collect it

---

Obituary

HUGH SPEAR PEMBERTON

M B Lpool, F R C P

Dr H S Pemberton, senior physician to the David Lewis Northern Hospital, Liverpool, died at his home at Neston, Wirral, on Jan 15 at the age of 65

He qualified in 1913 with first-class honours in medicine at Liverpool University, and joined the staff of the David Lewis Northern Hospital a year later as clinical pathologist During the 1914–18 war he served with the R A M C After demobilisation in 1919 he was appointed junior physician to the David Lewis Northern Hospital He took the M R C P in 1921 and was appointed a full physician in 1924 He also joined the staffs of the Liverpool Hospital for Women and of the Liverpool Radium Institute He was lecturer in clinical medicine at Liverpool University The whole of his active clinical life was thus associated with Merseyside, but his greatest devotion was given to the David Lewis Northern Hospital He was especially interested in dietetics, and his diabetic clinic, founded in 1922, was the largest in the district and kept outstanding records He followed closely the work of the dietitians and the diet kitchen, and he took the leading part in producing the *David Lewis Northern Hospital Diet Book*, first published in 1935 He was the first director of the hospital's biochemical laboratory He was elected F R C P in 1941. He retired from the hospital staff last year

A colleague writes "Pemberton was an outstanding teacher and there was always great competition among the undergraduates to be appointed to him as clinical clerks The meetings of all the members of the medical staff of the hospital over which he presided every week provided a very great stimulus to his colleagues and were a constant source of lively discussion His publications were chiefly concerned with diabetes and diseases of the peripheral vascular system, but he brought original and stimulating criticism to papers by his junior colleagues on a wide variety of subjects"

Dr Pemberton leaves a widow and a daughter

[1] *Birmingham Post*, Dec 29 1955

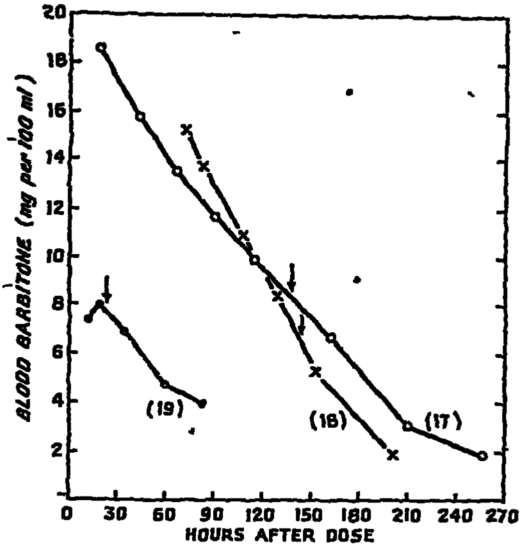

Fig 2—Fall in blood levels of 3 cases of barbitone poisoning The figures in parentheses indicate the case number, and the arrows the time at which consciousness was regained

Case-records

A Typical Case (no 20)

A man, aged 27, was found unconscious, having taken an overdose of butobarbitone the previous evening His progress in hospital is illustrated in fig 4 He was given a stomach washout on admission, but this yielded a negligible amount of barbiturate He passed no urine in the first 40 hours, but after intravenous therapy, including noradrenaline, he excreted 0 5 g butobarbitone in 15 hours At the end of the 2nd day he showed no sign of returning consciousness, and since his chest condition was causing anxiety he was given picrotoxin This produced no change in the rate of fall of the blood-butobarbitone level He recovered consciousness 90 hours after the dose, when the blood-level was 2 5 mg butobarbitone per 100 ml

An Exceptional Case (no 16)

A woman, aged 67, was found unconscious, having taken not less than 22 g barbitone 12 hours previously Respiration failed on the journey to hospital, and was re started by manual artificial respiration On admission to hospital all reflexes were absent, and the blood pressure was 90/50 mm Hg She was given nikethamide ('Coramine') and oxygen, and gastric lavage was performed Later respiration again failed, and, after tracheotomy, was maintained by an intermittent positive pressure apparatus The blood pressure was maintained by an intravenous infusion of noradrenaline Bemegr ('Megimide') in doses of 50 mg intravenously was given a total of 1 g, without apparent effect Tube feedin intermittent positive pressure, and noradrenaline infus were continued until the patient died, 96 hours after admissio Necropsy showed that death was due to pulmonary oeden and pneumonia

Barbiturate estimations of this patient are given in table

PATIENTS FOUND DEAD

Barbiturate levels of specimens taken from the patients found dead are shown in table v In only cases (58 and 59) were the blood barbiturate level

TABLE III—BLOOD-BARBITURATE LEVELS AT RETURN OF CONSCIOUSNESS

Barbiturate	Case no	Picrotoxin I V (mg)	Blood barbiturate at return of consciousness (mg per 100 ml)	Mean blood barbiturate (mg per 100 ml)
Phenobarbitone	1	Nil	7 9	
	2	Nil	7 8

	35	24	1 3	

significantly higher than those of *surviving patients* who had taken the same drug (table II) The C S F levels were lower than those of blood, and, in general, only small amounts of barbiturate were found in urine, liver, and kidney *Stomach and intestinal contents usually con*tained large amounts of barbiturate, contrasting strongly with the amount recovered by stomach washout from the surviving patients

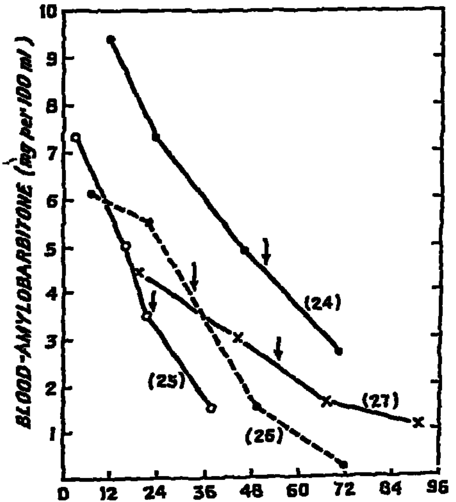

Fig 3—Fall in blood-levels of 4 cases of amylobarbitone poisoning The figures in parentheses indicate the case number, and the arrows the time at which consciousness was regained

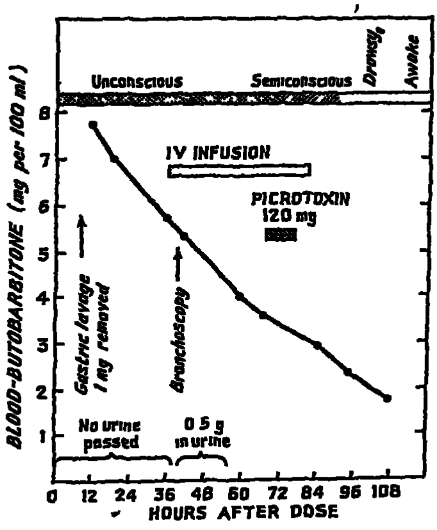

Fig 4—Progress of a typical case of barbiturate poisoning (case 20, butobarbitone)

Discussion

The reaction of barbiturates with cobaltous salts (Koppanyi et al 1934) is widely used as a qualitative test in cases of suspected poisoning, but it is relatively insensitive and may not be specific (Riley et al 1940) The test is usually applied to urine or gastric contents These specimens may be unreliable guides to the presence of barbiturate in the body and to the severity of the poisoning and, *furthermore*, are not always available from unconscious patients

Notes and News

HAROLD HILL HEALTH CENTRE

BETWEEN 1948 and 1954 a community of thirty thousand people was created at Harold Hill in Essex as part of the dispersal plan for the population of Greater London This new population brought with it a need for medical care, and a report by the professional committee of the Harold Hill Health Centre describes steps taken to meet it

In the early stages new practices were declared by the executive council and special doctors' houses with attached surgeries were built, but during early 1954 a health centre was completed This centre was originally intended to accommodate four practitioners, either singly or in partnership, as well as the personal health services and dental services provided by the local authority with certain clinics run by the North East Metropolitan Regional Hospital Board

After preliminary discussion with all the doctors who had care of patients on the estate, nine doctors (two in partnership) accepted invitations to lease the general practitioner accommodation, and a rota system was devised whereby each had the use of a suite—waiting room, consulting room, and examination room—for five sessions a week These practitioners share the services of a trained nurse and of the secretarial staff of the centre, and the report notes that, despite acknowledged differences of temperament between the doctors, coöperation has been perfect and no disagreements of importance have arisen during the first year s work

The doctors attending the centre retain their own surgery premises, but are provided with filing cabinets for the medical records of those patients who attend regularly at the centre Attendances at the centre have hitherto been smaller than those at the doctors' own surgeries but greater familiarity with the centre may reverse this. The centre will certainly play an increasing part in health education in the locality, for it is designed for a waiting room and an adjacent clinic room to be thrown together as a lecture hall Patients attending the centre will see their own doctor working side by side with clinic medical officers, while contact between the doctors and nursing staff is encouraged by a shared staff room This direct contact must surely improve the standard of health care in the community and it should encourage direct case work by the practitioner/health-visitor team In this respect it is an advantage that more practices than the four originally intended are brought into close touch with the local health authority

A SURGICAL CAUTERY

Mr J E Richardson, of the London Hospital, informs us that he has had good results with a variety of cautery originally made to the specifications of Mr W Calvert, M R C O G, and now manufactured in this country, with blades of various shapes and weights He has used it to cut stomach and small and large intestine, and finds that with practice the heat can be adjusted to cut down to the blood-vessels, which can then be dealt with individually It operates on approximately 12 volts (A C or D C) by means of a miniature element situated at the end of the shaft As the heating element is totally enclosed there is no risk of fire or accidental burning

The Oryx-Calvert' cautery is made by Oryx Electrical Laboratories at Brighton and is distributed by Antex, 3 Tower Hill London E C 3

University of Manchester

On March 23, at 5 P M , Lady Violet Bonham Carter, D B.E , will give the Lloyd Roberts lecture Her subject will be Of Human Greatness

University of Glasgow

On Jan 14 the following degrees were conferred .

M D—Thomas Jack A C Kennedy (with high commendation) J A Ritchie P M Shepherd (with commendation) D M Kissen (with honours), A J M Campbell * James Carswell

Medical Research Council

The council invite applications for the following fellowships for 1956–57

Rockefeller Travelling Fellowships—These fellowships are intended for graduates resident in this country who have had some training in research work in clinical medicine or surgery or in some other branch of medical science and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad before taking up positions for higher teaching or research in the United Kingdom Fellowships tenable in the United States will normally carry a maintenance allowance at the rate of $2700 per annum for a single fellow and $3900 per annum for a married fellow Provision will also be made for travelling and other approved expenses

Eli Lilly and Lederle Travelling Fellowships—These fellowships tenable in the United States are offered on terms and conditions similar to those attaching to the Rockefeller fellowships

Dorothy Temple Cross Fellowships in Tuberculosis—These fellowships offer special opportunities for study or research to British doctors who intend ' to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis The Fellowships will as a rule be awarded to candidates who wish to make their studies or inquiries elsewhere than in the United Kingdom They provide for the payment of a maintenance allowance at the rate of £650 per annum for a single fellow and £900 per annum for a married fellow An allowance will be made for travelling and other approved expenses

Alexander Pigott Wernher Fellowships in Ophthalmology and Otology—These fellowships are intended for doctors who are likely to profit by a period of work in ophthalmology or otology at a centre abroad before taking up positions for higher teaching and research in these branches of medical science The awards will normally be tenable for one year The fellowships provide for the payment of a maintenance allowance at the rate of £650 per annum for a single fellow or £900 per annum for a married fellow An allowance will be made for travelling and other approved expenses

Forms of application may be had from the secretary of the council, 38, Old Queen Street, London, S W 1, with whom applications must be lodged by March 15 (March 31 for the Pigott Wernher fellowships)

Determinations of barbiturate in tissues reported by other workers (Andrew and Neubauer 1947, Goldbaum 1948, Copeman 1954, Wright 1954) and in this paper are poor indications of the severity of the poisoning It is noteworthy, however, that the stomach and intestines of fatal cases often contain large amounts of barbiturate, and that this may indicate a rapidly rising blood-level at the time of death

Summary

The value of the determination of blood-barbiturate levels in cases of acute poisoning has been shown Qualitative tests for barbiturate in urine and gastric contents may be misleading

The levels of barbiturate in blood and other materials have been determined in 36 cases of acute poisoning Patients returned to consciousness with blood-levels of 5–9 mg per 100 ml of long acting, 1 7–4 2 mg per 100 ml of intermediate, and 1–2 mg per 100 ml of short-acting barbiturates Useful predictions of the time of return to consciousness can often be made

Picrotoxin therapy appeared to result in an earlier return to consciousness in some patients

The difference in blood-levels of patients on medicinal doses of barbiturates, and of those with acute poisoning, is discussed

Analyses of necropsy material from 10 persons found dead after ingestion of barbiturates are reported, and fatal blood-levels are discussed

We thank Dr A M Cooke, Dr F G Hobson, Dr P C Mallam, and Prof L J Witts for permission to study their patients and for access to case notes

"People have known for a long time that food sometimes goes bad, and that *children sometimes go wrong*, but, whereas they found out long ago that the way to keep the food sweet is to keep it in a cool place, they still entertain the most varied and often unsuccessful *ideas about how to* keep the children straight Bacteriology can now explain fairly exactly what happens when food goes bad, while psychology can tell us only a little about some of the things which can happen to make children go wrong, but that little is of immense value, because it is much harder to guess or find out what to do about the children than what to do about the food, and psychology has in fact disclosed errors in the care of children far more gross than anyone was making in the care of food But this knowledge is much harder to apply Engineers can make us a machine which will dispense coolness in the larder but no one will ever make us a machine which will dispense love and security in the home We have to do that for ourselves"—SIR GEOFFREY VICKERS, V C, *Listener*, *Jan 12, 1956, p 44*

ADRENALECTOMY AND THE METABOL RESPONSE TO INJURY

A W WILKINSON
M B, Ch M Edin, F R C S E
SENIOR LECTURER IN SURGERY IN THE UNIVERSITY OF ABERDEEN

THE normal complex metabolic response to injury modified by removal of the adrenal glands, but t administration of cortisone enables the totally adrenale tomised or hypophysectomised patient to react to inju with a metabolic response which in some respe resembles that of a healthy person with intact adren and hypophysis

In a patient maintained on a constant daily dose cortisone 200 mg after removal of the second adren gland Robson et al (1955) found increased urina excretion of nitrogen and potassium and decreas urinary excretion of sodium, as in postoperative patien with intact adrenal glands (Wilkinson et al 1949, 195 and concluded that this response was not due to increas secretion by the adrenal cortex

Mason (1955) found that patients undergoing tot hypophysectomy or adrenalectomy and maintained wi a constant daily dose of 80 mg of either corticotroph or cortisone also exhibited a similar metabolic respon to that found in postoperative patients with inta adrenals He concluded that the postoperative metabol changes do not depend solely on adrenal cortical activit

Neither of these reports includes a study of anoth operation preceding that of total adrenalectomy in th same patient Therefore I report here, in a patient wi recurrent carcinoma, the metabolic response followi bilateral ovariotomy and removal of one adrenal glan and, later, the removal of the remaining adrenal glan

Methods

Urine was collected in six hour specimens, urinar sodium and potassium levels were measured with a flam photometer, and nitrogen by the micro kjeldahl metho No attempt was made to maintain a constant intake o sodium or of potassium, the free consumption by th *patient of food* and *drink* was *recorded*, and the sodium potassium, and nitrogen contents were then calculate from the tables of McCance and Widdowson (1946) Fæces were not analysed The data for sodium potassium, and nitrogen are shown in the accompanyin *figure according to the method of* Reifenstein et al (1945) Intake is plotted down from the base line and output is then plotted up from the intake line Th area above the base line represents excess of output ove intake (negative balance), a clear area below the base line indicates an excess of intake over output (positive balance)

Case-report

In 1946 a married woman, aged 53, developed a left mam mary carcinoma, which was treated by radical mastectomy Her chest wall and axilla were subsequently treated wit X rays in February, 1947, and again in July, 1947, after nodule had appeared in the operation site She remained wel until 1952, when she noticed in the operation site anothe swelling, which in June, 1953, was treated by further radio therapy and with testosterone In March, 1954, the skin in *the treated area became* ulcerated and infected

On admission on Sept 6, 1954, her general condition was good, and the ulcer on her chest wall was 3 inches in diamete *and involved the ribs and intercostal* muscles There were no bony or glandular metastases

Operations—Laparotomy, bilateral ovariotomy, and lef adrenalectomy were *done on Sept 10, 1954, and* righ adrenalectomy on Sept 29, 1954

Postoperative course—During and after the first operation there was much fluctuation in *blood pressure*, but after the second operation the blood pressure was much less disturbed Noradrenaline was administered by slow intravenous infusion

THE RESULTS OF VALVOTOMY FOR AORTIC STENOSIS

C G BAKER
O.B.E., M.D. Lond F R C P
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL

MAURICE CAMPBELL
O.B.E., M.A., D.M Oxfd, F.R C P.
PHYSICIAN TO GUY'S HOSPITAL

From the Cardiac Department Guy's Hospital and the Institute of Cardiology, London

THE successful treatment of mitral and pulmonary stenosis inevitably raised the question of valvotomy for aortic stenosis Though the object is the same—to relieve the heart muscle from the strain of working against an obstruction—it presents a more difficult problem to both surgeon and physician

In all three conditions minor degrees of stenosis, though they give clear diagnostic signs, are well tolerated, and functional impairment of the heart and circulation is long in arriving, and may never appear In mitral stenosis, the effect on the pulmonary circulation gives some warning and often a liberal span of time before a critical degree of stenosis threatens the patient's life In uncomplicated pulmonary stenosis and in aortic stenosis, failure of the right and left ventricle respectively may be the first sign of danger and by then the optimum time for surgery has past In pulmonary stenosis the electrocardiogram generally helps to decide the best time for operation (Campbell and Brock 1955), and the pressure gradient across the valve can be measured by cardiac catheterisation

In aortic stenosis, the pressure gradient across the aortic valve is more difficult to obtain We do not yet know the stage at which symptoms justify the risk of operation, nor the significance that should be attached to left ventricular strains as demonstrated by the electrocardiogram Further the valve itself is likely to be calcified, and this makes operation difficult and increases the risk of valvular incompetence after operation Incompetence is not only more likely but also more serious with aortic valve than with the pulmonary valve, because it is subjected to higher pressure Nor can one welcome the approach through the wall of the left ventricle, which at present seems necessary

Our purpose in reporting the results of aortic valvotomy in the first 16 of our patients who were operated on up to December, 1954, is to try to solve some of these problems and to emphasise the difficulty the surgeon faces in treating advanced aortic stenosis Though good results can be obtained the risk of operation and the risk of producing aortic incompetence are both high

Condition of Patients Before Operation

We are here discussing patients with predominant aortic stenosis and not those with mitral stenosis as well In most patients who have had operations for both conditions, the mitral stenosis has been predominant the gradient across the aortic valve (measured at operation) has been less than in the present group with isolated aortic lesions, and the improvement after double valvotomy has been mainly due to relief of the mitral lesion Our predominantly aortic cases presented quite a different problem

As will be seen from table I, 12 of our 16 patients showed a similar clinical picture though the following 4 differ in some features

In case 8 there was more incompetence, with a blood-pressure of 120 70 mm Hg For this reason great hesitation was felt about operation, though it was strongly indicated by the patient's frequent anginal and syncopal attacks and was, in fact, successful for a time

Case 7 had a very large heart and gross congestive failure

Cases 11 and 15 were children with congenital aortic stenosis Operation was advised because of their increasing disability and anginal pain

Most of our patients were men between 40 and 50 years old, and the average age was 46 The onset of symptoms was less than five years before operation in all but 4 cases On the other hand the cardiac murmur had nearly always been noted much earlier, at an average age of 22 None of the patients, except case 8, had any evidence of rheumatic fever or of other valvular disease We need not discuss here whether the stenosis was congenital with secondary atherosclerosis and calcification, or whether these had developed on a valve that was normal in either case they can be distinguished from the obvious rheumatic condition where there is nearly always mitral stenosis and aortic incompetence

All the patients were in normal rhythm All had a high grade of stenosis with little or no incompetence Those with more incompetence were excluded because this indicates that the valve is less completely stenosed and that regurgitation would probably increase if the valve were opened more widely 8 of the 16 had a soft aortic diastolic murmur, but except in case 8 the degree of incompetence was insignificant All had classical signs of aortic stenosis, with a rough systolic murmur and thrill in the aortic area, a strong apical thrust, and a pulse that was slow-rising and generally small It is, however, sometimes difficult to take the

TABLE I—FINDINGS IN PATIENTS WITH AORTIC STENOSIS BEFORE VALVOTOMY

* These murmurs were noted while they were in the Army LV = Left ventricular RV = Right ventricular

cortical extract and did not occur in rats maintained with 1% saline solution only

Campbell et al (1953), who also used the urinary excretion of nitrogen as an index of the metabolic response to injury in rats, found that a similar increase in urinary nitrogen followed both fracture of a femur and implantation of cortisone acetate 25 mg, and that a further and similar increase followed both the implantation of cortisone acetate 50 mg and the combination of fracture of a femur with the implantation of cortisone acetate 25 mg In the present patient the second surgical trauma was less severe than the first, but it was expected that this would be amply compensated by the large dosage of cortisone, it is very surprising that after the second operation the nitrogen and potassium in the urine were respectively only half and a quarter as much as after the first operation

Since this patient was very ill with recurrent malignant disease, an important factor in reducing the urinary excretion of nitrogen after the second operation may have been the previous loss of nitrogen due to tissue katabolism after the first operation In addition, the daily intake of dietary protein was low for at least three weeks before the second operation, and it is well recognised that many of these patients are in negative nitrogen balance and depleted of protein, 4 of the 5 patients reported by Mason (1955) were in negative nitrogen balance before operation The reduced potassium loss after the second operation can be related in part to the smaller tissue katabolism indicated by the reduced urinary nitrogen loss

Comparing the metabolic effects of bilateral splanchnicectomy Moore et al (1955) found a smaller urinary nitrogen loss with increased sodium conservation after the second operation than after the first, their patient, however, did not suffer a large loss of sodium after the first operation I made a similar observation after the resuture of a disrupted laparotomy wound Moore et al suggested that the difference in response after the second operation might be a continuing effect of the first operation, and they discounted any likelihood that it might be due to adrenal "exhaustion" or insufficiency In the present patient the apparently abnormal response to the second operation may be the normal result of a second operation *after a short interval* and thus evidence of the success of cortisone as a substitute for the whole adrenal

After the second operation water loading by the intravenous infusion of 5% glucose solution was followed by diuresis Gaunt et al (1949) found that there was an increased reabsorption of water by the renal tubules after adrenalectomy and a diminished diuretic response to a water load Mirsky et al (1954) showed, however, that the increased antidiuretic activity of the plasma in adrenalectomised rats, maintained on 1% sodium-chloride solution, was abolished by the administration of cortisone The antidiuretic effect of adrenalectomy seems to have been similarly diminished in the present patient by the administration of large doses of cortisone Later, after the second operation, when the dose of cortisone was reduced there was a tendency to retain water, and it seems more likely that this was due to increased antidiuretic activity than to sodium conservation, since, because of the low daily intake of sodium, only a little sodium was retained in the body

Llaurado (1954) concluded that a "sodium retaining" and "potassium excreting" factor is excreted in the urine immediately after operation, concomitantly with a large loss of potassium and inversion of the urinary sodium potassium ratio Although he did not isolate aldosterone from urine after operation he suggests that aldosterone is the electrolyte controlling substance, and that an increased production of aldosterone is part of the normal endocrinological response to injury Evidence from only one patient must be viewed with the greate caution, yet the intense conservation of sodium afte adrenalectomy with large maintenance doses of cortisone suggests that either large doses of cortisone may have powerful sodium retaining activity or aldosterone may be produced elsewhere than in the adrenals Further comparison between the two stages of bilateral ovariotomy and bilateral adrenalectomy, with varied dosage of cortisone after the removal of the second adrenal, and with similar doses of cortisone after both operations, i clearly desirable and is being undertaken

Summary

The metabolic responses of a woman with recurrent carcinoma of the breast to bilateral ovariotomy and removal of one adrenal and to the removal of the remaining adrenal, although basically similar, showed large differences in degree

The urinary nitrogen and potassium were respectively only half and a quarter as great after the second as after the first operation, but sodium conservation was more complete and prolonged after the second operation

After adrenalectomy cortisone restores the ability to respond by diuresis to a large water load

These results indicate a need for caution in the interpretation of metabolic studies after adrenalectomy

I am indebted to Sister Duguid and her staff for the collection of the urine and measurement of food and fluid intakes, and to Miss Edna Simpson and Mr Gordon Shewan for their assistance in the analysis of the urines

ACUTE TUBULAR NECROSIS OF THE KIDNEY FOLLOWING ABORTION

G M Bull

Abortion procured by intra uterine douching with soapy water is one of the common causes of acute tubular necrosis of the kidney The factors bringing this about may be severe shock, infection (particularly with *Clostridium welchii*), and the circulation and renal excretion of heme pigments formed by hæmolysis The following 13 cases of abortion anuria were seen at the Hammersmith Hospital between 1947 and 1952, when we were studying anuria (Bull et al 1949, 1950)

7 of the patients admitted that intra uterine douching had been carried out either by themselves or by other persons 1 patient had had a therapeutic abortion in a nursing home by

she has been free from cardiac asthma and syncopal attacks for eighteen months, but she now has a significant degree of aortic incompetence

Case 10 —This man, aged 38, had led an active life and played tennis until two years previously, when, after running 200 yards for a bus, he collapsed and became unconscious He began having angina on hurrying and unless he stopped he soon lost consciousness during the next year the attacks of angina became more severe and frequent

At aortic valvotomy, the valve was split freely, and the pressure gradient was reduced from 94 to 59 mm Hg A year later he was able to do as much as before his collapse three years previously, he had no anginal pain or any suspicion of loss of consciousness He still showed inversion of the T wave in leads V5 and V6, as before operation

Case 11 —A boy, aged 6, with congenital aortic stenosis, had always been short of breath, but from the age of 4, when he could walk a mile easily, he became worse and developed anginal pain which was severe if he ran for 20 yards His heart was getting larger the cardiothoracic ratio in 1950 was 52%, but in 1953 it was 59%

At aortic valvotomy, the valve was felt to split widely with the expanding dilator and the pressure gradient fell from 128 to 12 mm Hg A year later he was able to run about with other boys There was less left ventricular preponderance and the T wave inversion had disappeared from leads I, II, and V4 and was much less in leads V5 and V6 There was now a soft aortic diastolic murmur, his blood pressure was 110/65, and his heart was no smaller

PATIENTS WHO WERE IMPROVED

5 patients gained some relief from the operation, but less than those classed as good results Case 1 has been described Case 6 had led a very active life including whaling in the Antarctic, but for two years he had been disabled by anginal pain He was somewhat better for the year after operation, but he died suddenly after severe anginal pain and a sharp fall of blood pressure Case 2 still has angina and dyspnœa on exertion, but he has had no syncope since operation three years ago and has been able to work which was not possible before None of the 3 patients showed any great change in the pressure gradient across their aortic valves after operation

Cases 13 and 16, on the other hand had moderate reductions in their systolic gradients the first has not improved as much as was hoped, probably because aortic incompetence has developed, while the second, though he is relieved of symptoms and is back at work, has an aneurysm of his left ventricle

PATIENTS WHO HAVE DIED

3 patients died at or soon after operation, and 3 some weeks or months later without much improvement The first 3 (cases 3, 4, and 5) were all men, aged 40–50, with the usual picture that has been described In case 4 the pressure gradient was reduced from 102 to 60 mm Hg but in the other 2 there was little change Cases 3 and 4 have been reported by Campbell and Kauntze (1953) as their cases 32 and 37 in the former the valve was bicuspid but in the latter it was tricuspid, and in both there was heavy calcification, there was no evidence of rheumatic disease of the other valves Case 5 had gross calcification of his aortic valve

The other 3 developed free aortic incompetence and this seemed the main reason for their deaths All 3 showed a good drop in the pressure gradient across the aortic valve at operation (table II)

Case 12 died four months after operation with left ventricular failure, there was a fracture across the calcified part of the aortic valve and the fibrous element was split, the mitral ring was dilated but there was no rheumatic disease

Case 14 developed free aortic incompetence and died four months after operation with right and left ventricular failure At necropsy the right posterior aortic cusp was found to be split obliquely, the mitral valve was healthy

Case 15 —This girl with congenital aortic stenosis had a large heart (cardiothoracic ratio 55%) and a slight incompetence when she was 7 years old Three years later she became more breathless and had anginal pain on walking uphill or into the wind, and two more alarming attacks led to all her activity at school being stopped At aortic valvotomy, the pressure gradient across the valve was almost abolished, but severe aortic incompetence and cardiac asthma developed and she died suddenly two weeks later

DISCUSSION

Some of the problems of valvotomy for aortic stenosis were first discussed by Smithy and Parker (1947) and by Brock (1950) Bailey et al (1952) emphasised the danger of regurgitation after incision of the valve and Larzelere and Bailey (1953) thought that good results were more likely in rheumatic than in congenital and atherosclerotic stenosis Later Bailey et al (1954) reported valvotomy in 62 patients, of whom 27 had aortic valve disease only In this group the operative mortality was 22%, and though many of the survivors were said to be better, it is not easy to know how much they were improved or how advanced the condition was before operation

Muller et al (1954), reporting the results in 16 cases of pure aortic stenosis (13 with calcification), thought that only half the patients were improved there were 2 deaths Logan and Turner (1954) held that surgical treatment should be advised before symptoms became severe their 9 rheumatic cases were somewhat similar to ours but 4 had coexisting mitral stenosis only 1 of these patients died and the others were said to be improved

Marquis and Logan (1955) reported the results of operation in 6 patients with congenital aortic valvular stenosis None died and most of them were improved, but 4 developed aortic incompetence In retrospect, Marquis and Logan thought it would have been wiser to postpone surgery in 3 of the 6 cases, but the immediate prognosis in the other 3 was bad enough to justify the risk of even severe aortic incompetence They concluded that progressive left ventricular strain or increasing heart size in growing children were indications for valvotomy

Many of these papers report a mortality rate that is not unduly high but they emphasise the risk of producing aortic incompetence In our experience, neither of these risks is serious with combined mitral and aortic stenosis but both are serious in older patients with pure aortic disease—whether they have trivial incompetence or not—probably because of calcification If one decides that this risk cannot justifiably be taken until a late stage, the surgeon is given a difficult problem and one must expect a high mortality

The decision is hard to make, because most patients do well for so many years that any great risk does not seem justified When deterioration starts, the time before death is often short, and the patient is gravely ill For example, 3 of our patients died (1 suddenly and 2 with heart failure) after a decision to operate had been reached

The poor prognosis and short duration of life after the onset of severe symptoms are well recognised (Kumpe and Bean 1948, Lewes 1951, Bergeron et al 1954, Mitchell et al 1954) Matthews et al (1955) estimate the period between the onset of severe symptoms and death at only one or two years compared with five to ten years in mitral stenosis

Our results after valvotomy for pure aortic stenosis are much less satisfactory than those for mitral stenosis and for pulmonary stenosis The 5 good results show that success can be achieved and emphasise the importance of the mechanical obstruction, but the 6 deaths (3 at the time of operation and 3 later) show the difficulties, even among those patients who were improved, 3 died within two years

One difficulty is that the deformity of the valve by calcification makes it hard to avoid producing aortic cortical extract and did not occur in rats maintained with 1% saline solution only

Campbell et al (1953), who also used the urinary excretion of nitrogen as an index of the metabolic response to injury in rats, found that a similar increase in urinary nitrogen followed both fracture of a femur and implantation of cortisone acetate 25 mg, and that a further and similar increase followed both the implantation of cortisone acetate 50 mg and the combination of fracture of a femur with the implantation of cortisone acetate 25 mg In the present patient the second surgical trauma was less severe than the first, but it was expected that this would be amply compensated by the large dosage of cortisone, it is very surprising that after the second operation the nitrogen and potassium in the urine were respectively only half and a quarter as much as after the first operation

Since this patient was very ill with recurrent malignant disease, an important factor in reducing the urinary excretion of nitrogen after the second operation may have been the previous loss of nitrogen due to tissue katabolism after the first operation In addition, the daily intake of dietary protein was low for at least three weeks before the second operation, and it is well recognised that many of these patients are in negative nitrogen balance and depleted of protein, 4 of the 5 patients reported by Mason (1955) were in negative nitrogen balance before operation The reduced potassium loss after the second operation can be related in part to the smaller tissue katabolism indicated by the reduced urinary nitrogen loss

Comparing the metabolic effects of bilateral splanchnicectomy Moore et al (1955) found a smaller urinary nitrogen loss with increased sodium conservation after the second operation than after the first, their patient, however, did not suffer a large loss of sodium after the first operation I made a similar observation after the resuture of a disrupted laparotomy wound Moore et al suggested that the difference in response after the second operation might be a continuing effect of the first operation, and they discounted any likelihood that it might be due to adrenal "exhaustion" or insufficiency In the present patient the apparently abnormal response to the second operation may be the normal result of a second operation after a short interval and thus evidence of the success of cortisone as a substitute for the whole adrenal

After the second operation water loading by the intravenous infusion of 5% glucose solution was followed by diuresis Gaunt et al (1949) found that there was an increased reabsorption of water by the renal tubules after adrenalectomy and a diminished diuretic response to a water load Mirsky et al (1954) showed, however, that the increased antidiuretic activity of the plasma in adrenalectomised rats, maintained on 1% sodium chloride solution, was abolished by the administration of cortisone The antidiuretic effect of adrenalectomy seems to have been similarly diminished in the present patient by the administration of large doses of cortisone Later, after the second operation, when the dose of cortisone was reduced there was a tendency to retain water, and it seems more likely that this was due to increased antidiuretic activity than to sodium conservation, since, because of the low daily intake of sodium, only a little sodium was retained in the body

Llaurado (1954) concluded that a "sodium-retaining" and "potassium excreting" factor is excreted in the urine immediately after operation, concomitantly with a large loss of potassium and inversion of the urinary sodium potassium ratio Although he did not isolate aldosterone from urine after operation he suggests that aldosterone is the electrolyte controlling substance, and that an increased production of aldosterone is part of the normal endocrinological response to injury Evidence from only one patient must be viewed with the greate caution, yet the intense conservation of sodium after adrenalectomy with large maintenance doses of cortisone suggests that either large doses of cortisone may have powerful sodium retaining activity or aldosterone may be produced elsewhere than in the adrenals Further comparison between the two stages of bilateral ovariotomy and bilateral adrenalectomy, with varied dosage of cortisone after the removal of the second adrenal, and with similar doses of cortisone after both operations, i clearly desirable and is being undertaken

Summary

The metabolic responses of a woman with recurrent carcinoma of the breast to bilateral ovariotomy and removal of one adrenal and to the removal of the remaining adrenal, although basically similar, showed large differences in degree

The urinary nitrogen and potassium were respectively only half and a quarter as great after the second as after the first operation, but sodium conservation was more complete and prolonged after the second operation

After adrenalectomy cortisone restores the ability to respond by diuresis to a large water load

These results indicate a need for caution in the interpretation of metabolic studies after adrenalectomy

Abortion procured by intra uterine douching with soapy water is one of the common causes of acute tubular necrosis of the kidney The factors bringing this about may be severe shock, infection (particularly with *Clostridium welchii*), and the circulation and renal excretion of heme pigments formed by hæmolysis The following 13 cases of abortion anuria were seen at the Hammersmith Hospital between 1947 and 1952, when we were studying anuria (Bull et al 1949, 1950)

7 of the patients admitted that intra uterine douching had been carried out either by themselves or by other persons 1 patient had had a therapeutic abortion in a nursing home by

In children with congenital aortic stenosis, valvotomy should be considered when they have anginal pain or syncope on exertion, when left ventricular strain is increasing, or when the heart is enlarging

In adults with isolated aortic stenosis, increasingly severe symptoms are indications for valvotomy before there is heart failure or irreversible fibrosis of the heart muscle The chance of success is greater if the valve is not calcified, but this is unusual

We are greatly indebted to Sir Russell Brock, without whose help this paper would not have been possible We should like to thank Dr R J Shephard, Dr P R Fleming, and Dr L Brotmacher for the measurements of ventricular and aortic pressures during operations

ACUTE MASTITIS

MAVIS GUNTHER
M.A., M.D Camb
RESEARCH WORKER, OBSTETRIC HOSPITAL, UNIVERSITY COLLEGE HOSPITAL, LONDON

Two kinds of acute mastitis associated with pregnancy and lactation are well recognised, the superficial and the intramammary (Waller 1938, Romanis and Mitchiner 1952), but their essential differences are often not appreciated

Superficial mastitis is here viewed as either a staphylococcal infection of the skin or a Montgomery tubercle which penetrates into the breast Intramammary mastitis, even when declared by an accompanying rigor, is believed to be non-infective at first, although staphylococcal infection may soon supervene Both kinds of mastitis are common, painful, and largely preventable

Incidence

The incidence of mastitis has been as high as 8 91% in the mothers giving birth in an area where the condition was notifiable (Fulton 1945), 7 0% in mothers delivered in hospital among a representative sample of Britain (Douglas 1950), and 2 6% in Newcastle upon Tyne (Spence et al 1954)

Ætiology

Two main views are held about their cause Waller (1938) emphasised the importance of sore nipple, and Macpherson (1943), Walsh (1949), and Czermac (1952) drew attention to the prime importance of stagnation and retention of milk The figures published by Blaikley et al (1953), though small, confirm the belief that the incidence can be reduced by antenatal and puerperal care

Present Investigation

The courses of the two diseases and the conditions associated with them in 129 cases seen in the two years from September, 1951, to September, 1953, were analysed and contrasted All the cases were in women delivered by the staff of University College Hospital and include all those which we treated, or of which we heard, in pregnancy or during or after lactation

The term mastitis is used here to describe not only frank cases but also the very least conditions which, for reasons given below, are held to be incipient mastitis There were 25 cases of superficial mastitis and 109 of intramammary, 5 patients had both types at some time In the two years there were 2701 deliveries under the care of the hospital Although the patients seen were not necessarily delivered in this period, the rates of incidence may be taken as 4 2% for intramammary mastitis and 1 0% for superficial mastitis, and the incidence of intramammary abscess was 1 1% In six months in 1955 the rates were superficial mastitis 1 0% and intramammary mastitis 0 9%, and there have been 1 intramammary abscess in pregnancy and 1 in lactation in 717 cases (2 1%)

SUPERFICIAL MASTITIS

Superficial mastitis could be seen to have begun, in all the patients coming early for treatment, either as an infected Montgomery tubercle or else as a spot on the areola or on the skin close to it As it progressed, a lump formed which was found to consist of pus, however early it was incised

The early course of the mastitis was slow, and those patients who came later for treatment could seldom say definitely when the inflammation had begun This slow early pace suggests that the causes should be sought in the preceding days rather than in the days of onset No patient in this series was seen to have superficial mastitis in the first ten days after delivery, but the frequency with which it arose in the next ten days after leaving hospital suggested that the cause lay in the earlier period

Those patients who came when the mastitis was established complained either of pain or of a lump Only 1 had pyrexia in the course of the illness, and her temperature only rose as she developed a superimposed intramammary mastitis (fig 1) Except in 4 patients whose lesion was seen before the indurated lump was as large as a pea, improvement did not last if the pus was not discharged either spontaneously or through an incision Unopened abscesses tended to track behind the nipple, and pus escaped out of the nipple of 1 patient Apart from this case, where mechanical difficulty prevented suckling and there was the risk that the baby might

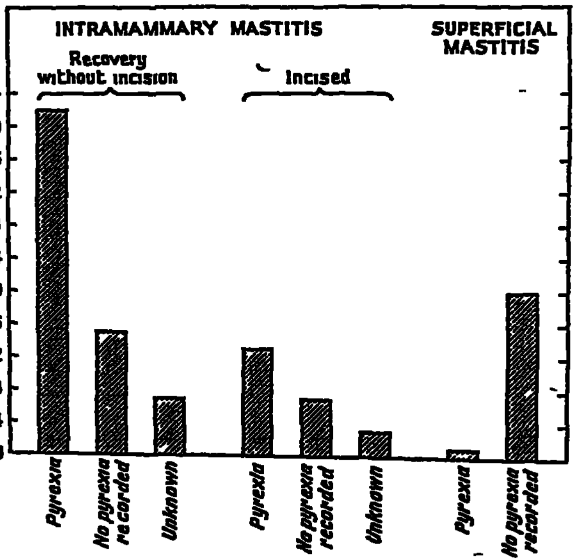

Fig 1—Pyrexia in intramammary mastitis does not mean pus, pyæmia, or poor prognosis

DURATION OF OLIGURIA AND DAY OF ONSET OF DIURESIS

11	11	15	384	18	
12	10	12	?		
13	15		560	17	Died

* Urinary output of less than 300 ml per day
† Urinary output of 1 litre or more per day

out by the insertion into the cervix of a commercial preparation containing medicated soap Severe abdominal pain and shock developed, and subsequently oliguria and signs of pelvic peritonitis The *intragastric drip feeding régime was instituted* No laboratory data were obtained The pelvic peritonitis was controlled by large doses of antibiotics, and she made a good recovery During convalescence mild right sided uveitis developed which responded to cortisone

Case 13 —A woman, aged 26, gave herself an intra-uterine douche of soapy water on Dec 3, 1948 This was followed by vaginal bleeding, vomiting, and oliguria She was admitted to hospital on Dec 12, and her uterus was evacuated the next day

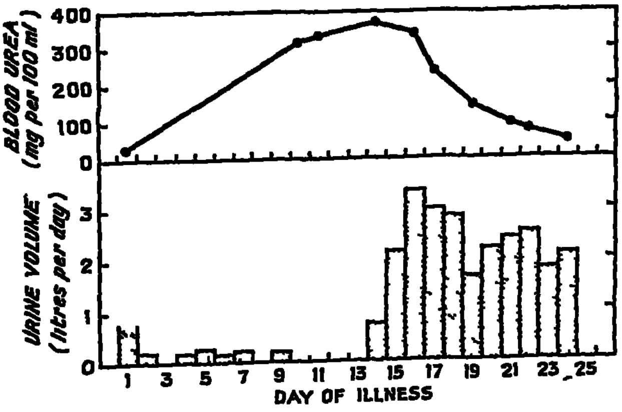
Treatment and progress —Initially she was treated by large amounts of intravenous fluids and by lumbar splanchnic blocks She then showed signs of fluid overloading and uræmia, and intragastric drip feeding was begun on Dec 14 We saw her on Dec 16 when diuresis was starting, the urinary output on Dec 18 was 500 ml Pulmonary œdema supervened, and she died on Dec 19

Necropsy showed acute tubular necrosis

Discussion

Early Treatment

The patient should be admitted to hospital as soon as possible and emergency treatment of shock instituted We saw no patient at the onset of her illness, there were delays varying from a few hours to as much as 14 days before admission to hospital, and there were further delays before the patients were seen by us 4 patients had blood-transfusions on admission for shock, but none had signs of a hæmolytic transfusion reaction Only 1 patient, who did not have a transfusion, had "bloody" urine at the onset of renal failure Several patients were thought to be jaundiced on admission but no supporting laboratory evidence is available In some patients (for example, case 7) shock was severe and prolonged, but in others (cases 1 and 6) renal failure developed insidiously, and there were delays of several days before their admission to hospital



Blood urea level and urine volume in case 7

Infection

Infection of the genital tract, peritonitis, and septicæmia are considerable hazards and may require careful treatment, particularly with antibiotics 2 patients had severe infections, these possibly influenced the development of renal failure

Case 5 had septicæmia due to *Cl welchii* which was controlled by penicillin and sulphathiazole When seen by us on the 10th day of her illness she showed signs of gross overloading with fluid, she was in coma and died before dialysis could be performed

Case 8 died from a flare up of peritonitis after she had had a diuresis and a fall in her blood-urea level from 396 mg to 80 mg per 100 ml High blood-levels of antibiotics are readily obtained during anuria, because of lack of renal excretion A fall in blood antibiotic level, due to diuresis, may have been responsible for death in this case

Oliguria and Anuria

All patients had anuria or severe oliguria for periods varying from 9 to 20 days and maximal blood-urea levels varying from 299 mg to 672 mg per 100 ml (see accompanying table)

In 5 cases there was necropsy confirmation of acute tubular necrosis, and in the 8 surviving patients the clinical course of the illness and the pattern of renal dysfunction were typical (Bull et al 1950) The accompanying figure shows the fall in the blood urea level after the start of diuresis in a 16 year old girl (case 7) who recovered Some of the other cases have been described previously (Bull et al 1949, 1950)

Until 1949 the emphasis in treatment in our unit was on the removal of waste products from the blood and the correction of electrolyte balance by dialysis with an artificial kidney Cases 2 and 3 had successful dialyses, but case 2 died of pyæmia probably caused by staphylococci introduced during dialysis, these organisms were resistant to the antibiotics then available

Renal Failure

Criminal abortion is a common cause of acute renal failure according to most workers Hamburger (1954), reviewing 100 cases of acute tubular nephropathy, noted that 39 were postabortive Elsewhere abortion seems to have accounted for a smaller proportion of cases of acute renal failure (Swann and Merrill 1953, Brun 1954), but in our experience abortion is as important a cause of renal failure as concealed accidental hæmorrhage of pregnancy, postoperative or traumatic shock, mismatched blood transfusion, or poisoning by mercury, &c

The lesion is probably caused by renal ischæmia brought about by blood loss or the severe pain following uterine douching In addition, the soap solution probably causes intravascular hæmolysis at the placental site, the resulting heme pigments circulate and form casts in the kidney Moreover phenol or another nephrotoxic agent may be incorporated in the douche and make the tubular necrosis worse Quinine used as an abortifacient, and infection with *Cl welchii*, both cause intravascular hæmolysis and shock and possibly renal failure subsequently, but both these causes are rare in our experience

Renal failure should be recognised early by the daily volume, specific gravity, and composition of urine, and the blood chemistry If rational treatment is applied (Bull 1955), renal failure should rarely cause death

2 patients died from water and electrolyte imbalance Case 13 was grossly overloaded with fluid early in the

If the first cause of intramammary mastitis is infection, what is the lump made of? In these cases removal of the secretion rather than the usual defences against bacteria brought cure. In all the cases under observation the secretion obtained by emptying the affected breast, even when the lump disappeared in the process, was milk, not pus. No baby was made ill by continuing to feed from the breast, and this was allowed for the first two days of illness and afterwards, if improvement was steady. There is no doubt that the lump consists of secretion and its containing breast tissue and is so much a part of the mammary gland that it is best palpated by the finger tips rather than the surgical flat of the hand. Although no patient in this series was operated on in what was literally the first flush of mastitis, cases have been seen in which a free incision through the lump has revealed apparently normal tissue.

The records of these cases of mastitis provide two other pieces of information which are obstacles to accepting infection as the cause. The concurrent apparently staphylococcal infection rate of 18%—4 patients with preceding superficial mastitis and 15 others (table I)—is little greater than the average for mother and child in the wards, whereas the rate among the patients with superficial mastitis was 60%. Then there is the remarkable fact that, although in every instance where the mastitis led to an abscess and this was incised the organism was *Staph. pyogenes*, there was not one pyæmic abscess, even though at the outset of the mastitis the patient's temperature had risen sharply to 104°F with a rigor. Either a second organism, never seen, causes the mastitis and, carried round the body, also causes a transient septicæmia, or else the cause of the pyrexia is non-infective. Attempts to find an organism have failed on the five occasions when blood was taken for culture as the temperature rose. The hypothesis of the independence of the pyrexia and infection is supported by the fact that prognosis is unaffected by pyrexia (fig. 1).

The subjective account given by patients during the pyrexia of mastitis is conspicuously like that of one suffering from an incompatible transfusion or from an intravenous dose of pyrogen. Typically the mother considers herself to be well or may already have noticed a slight headache or a tenderness in her breast and then, after emptying her breast by feeding or by artificial means, she suddenly collapses with pyrexia and a rigor. In the present series this happened in 5 patients, all of whom recovered entirely without abscess formation. A subjective account was that the patient "ached all over, down her legs and up her neck, and she felt as if she had been sleeping on boards." This reminds one of the days before the rhesus factor and pyrogens were known, when reactions to transfusions were common and every bottle of blood or of saline solution causing pyrexia was searched, usually in vain, for infection. The concept of bacteria causing pyrexia hindered doctors from thinking of other causes.

I suggest that, in intramammary mastitis, the sequence of events is as follows: retention of milk in a lobule of the gland either from failure to empty or from excess secretion, increased viscosity, or blockage of the duct; high pressure within the captive secretion; attempt at contraction of the myo-epithelial cells when the draught reflex comes into action; and leakage or even rupture of the alveoli or duct, with extravasation of the pent-up secretion. Since the breast is very vascular, the secretion may enter the blood-stream and have a pyrogenic effect comparable to that of cow's milk in humans. As Walsh (1949) has suggested, bacterial infection of extravasated milk and the surrounding tissue may then readily ensue and may also arise in merely pent-up secretion. There is some experimental backing for this hypothesis, for Selye et al. (1934) found that, in rats and mice, if the milk ducts were ligated and suckling maintained, milk was extravasated into the gland. In man the rigor or milder pyrexia usually comes on while the breasts are full or immediately after a feed and not in the two or three hours while the breasts are relatively empty. These are the times most likely to have been preceded by a draught reflex with its transient high intra-alveolar pressure.

Intravenous injection of a patient's own milk was not tried, because of the obvious difficulties not only of distress but of preparing an aseptic unaltered sample of milk. Milk 0.1 ml. given intramuscularly caused no pyrexia. To produce pyrexia where there is retention of milk previous sensitisation is apparently unnecessary, since such reactions were observed, and cured by emptying only, in 5 primiparæ in the first week after delivery. On the other hand, frank mastitis with a painful lump and a flush was seen in 7 cases without any detectable rise in temperature.

One argument in favour of a bacterial origin of mastitis is its common association with sore nipple. This is not convincing, for soreness usually develops when the breast is not taken properly, owing to its poor shape or to faulty posture of either the mother or the baby; these same factors, as Cruickshank (1942) has pointed out, also cause faulty emptying. In addition, soreness may make adequate emptying difficult, and trauma caused by emptying may be followed by mastitis. Furthermore, mastitis is seen where there has been no lesion of the nipple (Macpherson 1943), in pregnancy (2 cases in the present series), and where the baby has not been put to the breast at all. It can arise most unhappily in the breast of a woman given inadequate œstrogens to suppress lactation after a stillbirth.

Reasons have been given for rejecting the hypothesis of bacterial invasion as the first cause of intramammary mastitis. The histories of the patients support the hypothesis of retention. In common with Isbister's (1952) cases, factors or events conducive to faulty emptying were unduly common among the 109 women in whom this form of mastitis developed. There were 130 attacks after delivery. The 30 which developed during the ten-day lying-in period (and therefore under observation) were all associated with one or more of the following conditions: excess secretion with engorgement and much manual expression; sore nipples in breasts with poor protractility; an ill or small baby; physical obstruction to removal of milk (e.g., an adenoma and a scar); fear of giving the breast (in patients with healed pulmonary tuberculosis or with close relations who had had breast abscesses); and puerperal psychosis (2 cases).

Similar causes were found where mastitis arose later in lactation. 8 attacks followed resting sore nipples; 4 arose from physical obstruction; 5 from acute anxiety in the mother; and in 17 patients mastitis developed on twenty-two occasions after interruptions due to family emergencies or cutting down the number or duration of feeds or giving supplementary feeds without regard to the breast secretion. Most of these interruptions were made on medical advice. One patient provided an example of a condition which has been seen outside this series: when the area of retention yielded its milk to the 'Humalactor,' small pearly objects were seen which proved to be agglutinates of colostrum bodies and may have caused obstruction. Their origin is unknown, but in vitro colostrum bodies agglutinate on cooling.

Failure to keep the breasts emptied during weaning preceded fourteen attacks of mastitis: 4 patients did not attempt to empty the breast at all after starting a course of œstrogens; 5 were given inadequate doses of œstrogens; and 5 just ceased to put the baby to the breast and sought no help, for fear of having to continue feeding. This reckoning of precipitating causes leaves 29 cases with no clear cause; included in their number are some patients who seem either to have a predisposition or

† Urinary output of 1 litre or more per day

out by the insertion into the cervix of a commercial preparation containing medicated soap Severe abdominal pain and shock developed; and subsequently oliguria and signs of pelvic peritonitis The intragastric drip feeding regime was instituted No laboratory data were obtained The pelvic peritonitis was controlled by large doses of antibiotics, and she made a good recovery During convalescence mild right sided uveitis developed which responded to cortisone

Case 13 —A woman, aged 26, gave herself an intra-uterine douche of soapy water on Dec 3, 1948 This was followed by vaginal bleeding, vomiting, and oliguria She was admitted to hospital on Dec 12, and her uterus was evacuated the next day

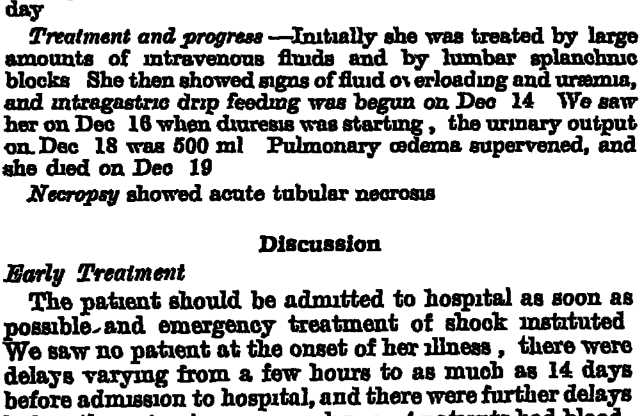
Treatment and progress —Initially she was treated by large amounts of intravenous fluids and by lumbar splanchnic blocks She then showed signs of fluid overloading and uræmia, and intragastric drip feeding was begun on Dec 14 We saw her on Dec 16 when diuresis was starting, the urinary output on Dec 18 was 500 ml Pulmonary œdema supervened, and she died on Dec 19

Necropsy showed acute tubular necrosis

Discussion

Early Treatment

The patient should be admitted to hospital as soon as possible, and emergency treatment of shock instituted We saw no patient at the onset of her illness, there were delays varying from a few hours to as much as 14 days before admission to hospital, and there were further delays before the patients were seen by us 4 patients had blood-transfusions on admission for shock, but none had signs of a hæmolytic transfusion reaction Only 1 patient, who did not have a transfusion, had "bloody" urine at the onset of renal failure Several patients were thought to be jaundiced on admission but no supporting laboratory evidence is available In some patients (for example, case 7) shock was severe and prolonged, but in others (cases 1 and 6) renal failure developed insidiously, and there were delays of several days before their admission to hospital



Blood urea level and urine volume in case 7

Infection

Infection of the genital tract, peritonitis, and septicæmia are considerable hazards and may require careful treatment, particularly with antibiotics 2 patients had severe infections, these possibly influenced the development of renal failure

Case 5 had septicæmia due to *Cl welchii* which was controlled by penicillin and sulphathiazole When seen by us on the 10th day of her illness she showed signs of gross overloading with fluid, she was in coma and died before dialysis could be performed

Case 8 died from a flare-up of peritonitis after she had had a diuresis and a fall in her blood urea level from 396 mg to 80 mg per 100 ml High blood-levels of antibiotics are readily obtained during anuria, because of lack of renal excretion A fall in blood antibiotic level due to diuresis, may have been responsible for death in this case

Oliguria and Anuria

All patients had anuria or severe oliguria for periods varying from 9 to 20 days and maximal blood urea levels varying from 299 mg to 672 mg per 100 ml (see accompanying table)

In 5 cases there was necropsy confirmation of acute tubular necrosis, and in the 8 surviving patients the clinical course of the illness and the pattern of renal dysfunction were typical (Bull et al 1950) The accompanying figure shows the fall in the blood urea level after the start of diuresis in a 16-year-old girl (case 7) who recovered Some of the other cases have been described previously (Bull et al 1949, 1950)

Until 1949 the emphasis in treatment in our unit was on the removal of waste products from the blood and the correction of electrolyte balance by dialysis with an artificial kidney Cases 2 and 3 had successful dialyses, but case 2 died of pyæmia probably caused by staphylococci introduced during dialysis, these organisms were resistant to the antibiotics then available

Renal Failure

Criminal abortion is a common cause of acute renal failure according to most workers Hamburger (1954), reviewing 100 cases of acute tubular nephropathy, noted that 39 were postabortive Elsewhere abortion seems to have accounted for a smaller proportion of cases of acute renal failure (Swann and Merrill 1953, Brun 1954), but in our experience abortion is as important a cause of renal failure as concealed accidental hæmorrhage of pregnancy, postoperative or traumatic shock, mismatched blood transfusion, or poisoning by mercury, &c

The lesion is probably caused by renal ischæmia brought about by blood-loss or the severe pain following uterine douching In addition, the soap solution probably causes intravascular hæmolysis at the placental site, the resulting heme pigments circulate and form casts in the kidney Moreover phenol or another nephrotoxic agent may be incorporated in the douche and make the tubular necrosis worse Quinine used as an abortifacient, and infection with *Cl welchii*, both cause intravascular hæmolysis and shock and possibly renal failure subsequently, but both these causes are rare in our experience

Renal failure should be recognised early by the daily volume, specific gravity, and composition of urine, and the blood chemistry If rational treatment is applied (Bull 1955), renal failure should rarely cause death

2 patients died from water and electrolyte imbalance Case 13 was grossly overloaded with fluid early in the

incised if pus is found Like Saner (1950) we have been impressed by the benefits of a small radial skin incision, which rarely needs to be as long as 1 inch If the breast is still secreting milk, emptying should have been maintained and done not more than an hour before operation By this means the outline of the lump is delineated, and the surgeon can be certain of the extent of the abscess and avoid opening up loculi Aspiration without incision, where tried, has had to be followed by incision, and local penicillin injections have produced lasting indurated lumps in the breast without curing

A method introduced by Miss Aileen Dickins of dressing abscess wounds was adopted in which ribbon gauze, newly dipped in sterile penicillin cream base, is led into the cavity and left untouched for forty-eight hours The discharge of pus, provided the gauze constitutes a wick and not a pack, is very satisfactory, and the dressing causes the minimum of pain to the patient All patients needing incision were admitted to hospital

The antibiotic of first choice for preventing infection has remained penicillin (table III) In contradistinction to superficial abscesses, intramammary mastitis appears still to be protected from infection by aqueous penicillin 1 0 mega unit daily or 0 5 mega unit twice daily from infection Once penicillin is deemed necessary, the dosage should be maintained for at least four days When infection has probably taken place already, aureomycin is used

Course of Infection

The infecting organism in all abscesses which were incised was *Staph pyogenes* and, except for secondary infection after incision, it was the only organism found in all the cases I have seen in fifteen years This conforms with the experience of Macpherson (1943), Walsh (1949), Saner (1950), and Isbister (1952) Duncan and Walker (1942) and Cunliffe (1949) have shown that *Staph pyogenes* is also found in the noses and throats of babies very soon after birth, and discussion has often arisen about the source of infection—does the breast give it to the baby, or the baby to the breast ?

Staphylococci, even virulent pathogens, appear to be protean, and from the infected person's point of view the size of the infecting dose of organisms appears important In terms of the organism the heavy dose derives from where the organism can multiply If it is conceded that staphylococci abound wherever there is stale breast milk or colostrum—in the pent up secretion of the breast, in the neonate's nasopharynx, and on the finger-tips and in the eyes, where colostrum and milk may easily get, and even in witch's milk—it seems reasonable to postulate that breast secretion is a vehicle of a growth promoting system (either a combination of factors or, like bifidus factor, a single substance) which affects *Staph pyogenes* The remarkable fact is that where breast secretion is pent up, even without the aid of a skin lesion or trauma, in regions remote from airborne organisms, even at the periphery of the gland in pregnancy, staphylococci establish themselves and may cause an abscess If indeed stale secretion contains an almost specific means of promoting the growth of staphylococci, the sepsis rate of neonatal skin may be expected to rise where the expression of colostrum is not followed by adequate washing of the hands The determining factor of clinical infection would then be the provision for the organisms' multiplication, which is less common, rather than the arrival of the organism, which is almost inescapable The inhibitory qualities against bacteria which fresh colostrum possesses do not rule out the possibility that fresh or altered secretion contains growth promoting substances Auclair (1954) has suggested that bovine colostrum may contain specific growth promoting substances for *Streptococcus agalactiae*

Prophylaxis

Prevention of intramammary mastitis consists in the *avoidance of retained secretion* In point of time antenatal treatment for poor protractility of the nipple comes first This enables the baby to take the breast vigorously and effectively from within a few hours of birth Antenatal expression of colostrum puts control of excess secretion into the mother's hands during lactation After delivery engorgement should be avoided, for it is often at this stage that an unemptied lobule becomes unemptiable

Since this investigation ended, a routine has been introduced which almost completely avoids engorgement Each woman, except those aged more than 35 and those who have been shocked or who have been delivered by cæsarean section, receives two tablets of stilbœstrol 0 25 mg within two hours of delivery and one tablet twenty-four hours later By this method and the occasional use of the humalactor, handling of the breasts before the fifth day by either the mother or the nurse has been largely eliminated These methods are defeated if care is not taken to see that the baby takes the breast properly, and this duty of the midwife is increased where pain from episiotomy or following obstetric interference immobilises the mother

The proper protractility of the nipple and the proper position of the baby at the breast are also safeguards against sore nipple and its sequelæ Demand feeding in the early days and night feeding from the breast also help, and anyone who sees the distension of the mother's breasts in the puerperium after eight hours at night in which the baby has not been breast fed must wish that hospital routine, where demand feeding may have drawbacks, should provide for the mother to feed her baby at 3 or 4 A M and then sleep until 7 A M

Milk retention and mastitis during lactation would often be avoided if those advising on infant feeding would recognise that the rate of secretion usually remains approximately constant day in day out Any event which reduces the amount of milk withdrawn—the dropping of a feed, or the giving of supplementary feeds—may be followed by mastitis, unless the mother has the knowledge and skill to avoid retention The time of weaning was shown in this series to be one of vulnerability There appear to be three requirements adequate œstrogens, judgment in keeping the breasts empty while the œstrogens take effect, and the need to accept the mother's intention to discontinue feeding Are there those who almost view mastitis as a punishment on the mother ?

Œstrogens given to suppress established lactation do not take much effect in the first twenty-four hours Although there is much individual variation, the mother should breast-feed her baby as usual on the day of starting treatment, about three times on the next day and twice on the next If the course of œstrogens is not tapered or is short, lactation may return at the time of œstrogen-withdrawal bleeding Since our practice over four years has been to give the following course, no patients have had mastitis with this method of

SULPHÆMOGLOBINURIA DURING ADMINISTRATION OF STIBOPHEN

The accidents which sometimes happen during the treatment of bilharziasis with antimonial compounds, especially stibophen ('Fouadin,' 'Repodral,' 'Fantorin'), cause much concern to those engaged daily in treating the infected population The sudden collapse, which is nearly always fatal in a few hours, has often been ascribed to sudden heart-failure We, however, suspected that there must be another factor to explain the sudden onset and the symptoms of shock

During the past few years we have investigated blood-antimony levels without being able to correlate them with the sudden death, the patients who died had normal amounts of antimony in their organs Recently the case reported here was associated with hæmoglobinuria and sulphæmoglobinuria Subsequently we found two more cases of hæmoglobinuria developing during treatment with stibophen

Case-report

A man, aged 32, and weighing 8 st $2^1/_2$ lb, with painful micturition and terminal hæmaturia, had had a course of intravenous tartar emetic five years ago and a course of intramuscular stibophen a year before admission for antibilharzial treatment

On examination he had nothing abnormal in his heart, chest, or abdomen His Hb was 65% (Sahli) before treatment Ova of *Schistosoma hæmatobium* were present in his urine

Treatment and Collapse—He was given 3 75 ml of a 6% solution of stibophen intramuscularly daily for eight days On the eighth day, at 10 30 A M (half an hour after the last injection) he collapsed, with pulse rate 120 and blood pressure 130/90 mm. Hg, and soon passed into coma with pulse almost imperceptible He was deeply cyanosed and had blotchy reddish areas all over his body His heart was dilated, and a weak systolic murmur was heard over the apex Coarse crepitations in both bases, with signs of consolidation, were detected Liver and spleen were palpable Oxygen inhalation was administered After an hour the patient regained consciousness and his pulse became palpable Although his general condition improved, he had convulsions occasionally At 2 P.M he was somewhat irritable and wished to urinate but could not do so Catheterisation produced 150 ml of port-wine coloured urine, which contained few red blood cells and numerous granular casts Spectroscopy of the urine revealed sulphæmoglobin and oxyhæmoglobin The patient's pulse rate was 110 and his temperature 101 3°F At 3 P M he was quiet but felt chilly He was therefore placed in an electric cradle intermittently He passed unaided 250 ml of port-wine coloured urine, whose condition was unchanged Next morning he passed 400 ml of urine, still port-wine coloured but of a lighter tint During the day the urine became gradually clearer, approaching the normal amber colour but still containing a brownish sediment of granular casts and traces of sulphæmoglobin and oxyhæmoglobin

Laboratory Findings—Hb 40%, red cells 2,820,000 per c mm, white cells 21,400 per c mm (neutrophils 93%, lymphocytes 7%), cephalin cholesterol flocculation test positive, thymol turbidity 10 units, blood-urea level 80 mg per 100 ml, blood bilirubin level 0 9 mg per 100 ml No malaria parasites were found in the blood

Progress—On the fourth day the urine still contained albumin and numerous granular casts, it was of low specific gravity (1 008) and sterile on culture. The icterus index was 8 units, and the blood-bilirubin level 0 5 mg per 100 ml On the ninth day the urine contained granular casts but no sulphæmoglobin, and the blood contained no malaria parasites and gave a negative Wassermann reaction, and the fragility of the red cells was within normal limits Radiographically the lungs proved normal except for slight increase in vascular and lymphatic markings From the fourth day onwards the patient's temperature declined gradually to normal level on the tenth day After a month his urine contained no casts or urobilinogen, and there was no evidence of sulphæmoglobin or of oxyhæmoglobin, blood urea level 38 mg per 100 ml, cephalin cholesterol flocculation test negative, thymol turbidity 4 units, Hb 80%, red cells 4,216,000 per c mm, white cells 8800 per c mm (eosinophils 25%, neutrophils 54%, lymphocytes 20%, monocytes 0%, basophils 1%)

Discussion

Although this condition is rare, it is necessary to draw attention to it It is noteworthy that the patient did not complain of any side effects until he received the eighth injection The clinical picture was of severe shock with acute intravascular hæmolysis, in addition a patch of pneumonic consolidation was present—a condition which is known to develop occasionally during antibilharzial treatment and has been ascribed to disintegration of the worms The urine was characteristic of acute hæmoglobinuria, and on spectroscopy proved to contain sulphæmoglobin and oxyhæmoglobin

The patient said that for a long time before the injections he had not taken any medicine which could cause this acute sulphæmoglobinuria The only explanation for this hæmolysis is the possible action of the sulphonic group in the stibophen on a susceptible person There was also no relation to any of the known hæmoglobinurias, as shown by the laboratory findings We have also found that stibophen stored for a long time is apt to undergo molecular dissociation and become toxic

New Inventions

AN INSTRUMENT RACK FOR CASUALTY SURGERY

To accelerate the preparations for casualty suturing and other minor surgical operations, a rack has been designed which will hold the few instruments commonly needed (figs 1 and 2) If kept filled in the casualty department it can be placed bodily in the steriliser when required for use, and can be lifted out by the handle, this is fixed at the point of balance and is made to fit the end of Cheatle's forceps

Construction is of one piece of 22 S W G polished stainless-steel sheet, with a handle of $^1/_8$ in stainless steel wire, bent and riveted in position Slots are cut to hold the instruments, those at each side of the rack have spring retainers (part of the single steel sheet) to hold scalpels firmly so that the blades cannot come into contact with other instruments in sterilisation (a too common cause of blunting)

One end of the rack has slots to hold 2 scalpels, 1 needle-holder, and 2 pairs of dissecting or toothed forceps, while the other has four slots to hold Spencer Wells's or Lane's forceps or scissors, as required The over-all dimensions of the rack are 10 in by $4^3/_4$ in

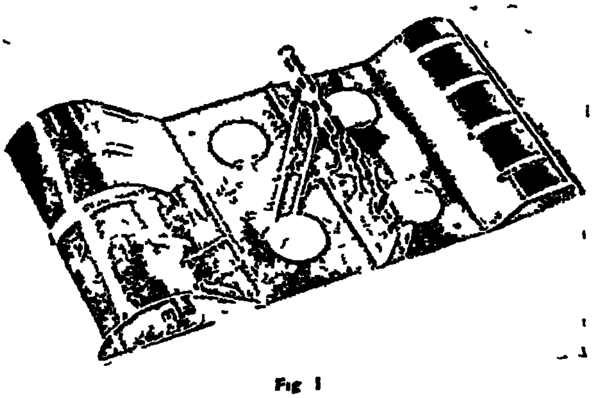

Fig 1

(where known) and their state of consciousness, are shown in table II For each barbiturate the blood-level appeared to be related to the degree of consciousness of the patient Analyses were made at different times after the dose, and it is therefore difficult to detect any absolute correlation between dose and blood-level However, long acting barbiturates produced higher blood-levels than similar doses of the short-acting ones For example, cases 1 and 34 had taken comparable amounts of phenobarbitone and pentobarbitone, yet their blood-levels at similar times after the dose were 10 2 and 6 1 mg per 100 ml respectively

The fall in blood-levels in 4 patients who had ingested different barbiturates is illustrated in fig 1 Blood-levels of the long acting drugs were higher, and the rates of fall slower, than those of the short acting ones

Thus in case 17 the blood level was 18 5 mg barbitone per 100 ml 19 hours after the dose, and 1 9 mg per 100 ml 10 days later when the patient had recovered

Case 3 was admitted to hospital within 2 hours of ingesting phenobarbitone, and the blood level continued to rise for about 12 hours 7 days after taking the drug the patient was awake, but the blood still contained 4 0 mg phenobarbitone per 100 ml.

Patients who had taken short acting barbiturates usually recovered more rapidly, for example, in case 34 only 0 7 mg pentobarbitone per 100 ml blood remained 3½ days after the dose

The rates of fall of blood-levels in patients who had taken the same barbiturate were similar but showed some individual variations, depending on the dose and the treatment given Results for 3 patients who had ingested barbitone are given in fig 2, the rates of fall are similar, although the peak blood-levels (18 5, 15 1, and 8 0 mg per 100 ml) differed considerably 2 of these patients (cases 17 and 18) remained unconscious for 6 days Fig 3 shows similar results, obtained from 4 patients after ingestion of amylobarbitone, in whom the peak blood-levels were 9 4, 7 3, 6 1, and 4 4 mg per 100 ml; these patients all regained consciousness within 2½ days

TABLE II—HIGHEST BLOOD BARBITURATE LEVELS FOUND IN LIVING PATIENTS

U = unconscious S = semiconscious D = drowsy A = awake

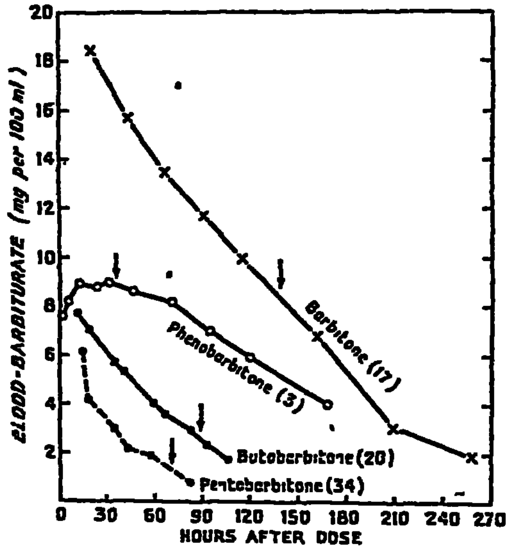

Fig 1—Fall in blood levels of different barbiturates. The figures in parentheses indicate the case number, and the arrows the time at which consciousness was regained

The blood-barbiturate levels of 23 patients at their return to consciousness are given in table III The mean levels are 7 mg (±2 mg) per 100 ml for the long-acting, 3 mg. (±1 mg) per 100 ml for the intermediate, and 1–2 mg per 100 ml for the short-acting barbiturates These conclusions are also illustrated by fig 1 and table II

Effect of Picrotoxin

Treatment of these patients varied considerably Picrotoxin was the analeptic most commonly used, but this did not appear to influence the rate of fall of blood-barbiturate levels Table III suggests that patients who were treated with picrotoxin regained consciousness at blood-levels slightly higher than those of other patients who had taken the same drug, but the data are insufficient for statistical analysis In 2 cases of phenobarbitone poisoning (nos 2 and 3) the blood-levels, and their rates of fall, were similar, case 2 was unconscious for 82 hours and his blood level was 7 3 mg per 100 ml when he regained consciousness, but case 3 was treated with picrotoxin, was unconscious for only 36 hours, and his blood-level was 8 9 mg per 100 ml when he regained consciousness

Gastric Contents

Quantitative analyses of gastric contents and washings were made in 21 patients The volumes of these contents were variable and the barbiturate levels ranged from 1 to 1500 mg per 100 ml The total amount of barbiturate removed by gastric lavage was 0 1–119 mg, and it was the equivalent of less than 4% of the dose in the 6 cases in which data were complete When this treatment was given more than 12 hours after the dose the total amount of barbiturate removed was insignificant, irrespective of the dose

Urine

Single specimens of urine from many of these cases were also analysed Except in 1 case (no 16—see below), the highest barbiturate level found was 42 mg barbitone per 100 ml 71 hours after the dose (case 18) In most cases of phenobarbitone poisoning the level in urine was less than 10 mg per 100 ml, but no correlation between urine levels and the degree of unconsciousness could be detected.

Many English books still advise that the breasts should be palpated with the flat of the hand, though this advice stems from a wrong translation of Velpeau's French

The book can be read as a whole, and not just as an encyclopædia It may not give the reader a very original point of view, but it achieves its object of summarising the main facts and the important questions about breast cancer, as an experienced surgeon sees them

The Boke of Chyldren

THOMAS PHAIRE Edited by Prof A V NEALE, F R C P, and H R E WALLIS, M D Edinburgh E & S Livingstone 1955 Pp 76 7s 6d

PUBLISHED in 1545, this was the first book on pædiatrics ever written by an Englishman and one of the earliest medical books to be published in the English language At that time the world was beginning to emerge from the darkness of the Middle Ages printing had been invented a hundred years before, and Vesalius's *Fabrica* had just appeared, but books written by Avicenna and Galen were still in everyday use

Phaire was born about 1510 probably in Norwich He went to Oxford to study medicine and to Lincoln's Inn to study law He started to practise medicine about 1540 and took his M B and doctorate at Oxford twenty years later He was also a solicitor and Member of Parliament He lived in Kilgerran in Pembrokeshire and died there in 1560

This is an exact copy of the first edition with the original spelling

"The gut called of the latines rectum intestinum, falleth out at the foundament, and cannot be gotten in agayne without peine and labour" "Of smal pockes & measilles The best and most sure helpe in this case is not to meddle with anye kynde of medicines, but to let nature work her operacion" Phaire says that the cause of ulceration of the head is from sides of bacon or salt beef falling from the hooks in the ceiling (Then, as now, accidents at work and in the home were important) The author's credo is "Here to doo them good that haue most nede, that is to saye children"

The editors and publishers have earned our thanks by reprinting this book of quaintness and charm

Somme de médecine contemporaine

Vol III *La thérapeutique* Editors Prof ANDRÉ LEMAIRE, Prof GREGORIO MARAÑÓN Prof JEAN LA BARRE, Prof ARVID WALLGREN Nice Les Éditions Médicales 1955 Pp 390

THIS is the third volume of the Contemporary Medicine series, prepared under the direction of the late Rene Leriche, which will be completed by a fourth volume on Medicine in Modern Life In a foreword, Prof André Lemaire puts the case for more international "pooling" of methods of treatment, but he condemns those periods of "inflation" which he thinks all active treatments pass through

The early chapters on general subjects include a short but interesting history of therapeutics by Prof Jean La Barre The rest of the book is divided according to the different systems of the body or different forms of treatment, ranging from phytotherapy to stomatology Curiously enough there is little mention of radiotherapy or radioactive isotopes There is no index except for a list of authors with a short "bio bibliography" of each and a list of names quoted in the text

Social Casework in Marital Problems

The Development of a Psycho dynamic Approach A Study by a Group of Caseworkers London Tavistock Publications 1955 Pp 199 15s

THIS is an account by six caseworkers of the origins, development, and working of the Family Discussion Bureau, which is a child of the Family Welfare Organisation Society and the Tavistock Clinic

The Bureau is rather like the Marriage Guidance Council —but with a difference Its caseworkers are not counsellors or advisers but have had some training in the school of analytic psychology, and have analytically trained psychiatrists immediately available for consultation They endeavour to work out with marriage partners in difficulties the nature, psychological content, and origins of their emotional disharmonies If both partners are willing, each has his or her own caseworker, and the situation revealed is discussed by the caseworkers and a psychiatrist in conference The expectation is that many interviews will be needed in a given case, though occasionally much good springs from a few or even a single interview when the troubled partner has been able to clear his own mind by talking to a receptive but uninvolved listener, who neither adjudicates nor takes sides

Cases, both short and long, are used to illustrate the various problems, their working out, and the measure of success achieved Some attempt is made to assess statistically the results of five years' development and work

The material is presented with modesty and candour and makes interesting and instructive reading

Operative Dental Surgery

7th ed J B PARFITT, M R C S, F D S R C S, consulting dental surgeon, Guy's Hospital, W E HERBERT, M R C S, F D S R C S, professor of dental surgery in the University of London at the hospital London Edward Arnold 1955 Pp 524 45s

BASED on lectures delivered at Guy's Hospital by Mr Parfitt, this book first appeared just over thirty years ago Its scope, which was to give a concise account of the technical procedures of dental surgery with enough theoretical background to explain the underlying principles, has remained unaltered, and there is no other English book which covers precisely the same range of subjects

The chapters on filling materials and cavity preparation are good, but that on the uses of gutta percha seems redundant in the present day, and a fuller account of the auto polymerising acrylic resins would be welcome Crown and bridgework are dealt with adequately for all but the specialist An excellent discussion of the pulpless tooth and "focal sepsis" will interest both doctors and dentists called upon to decide whether or not dead teeth should be retained The ætiology of dental caries is oversimplified and there is no account of some of the more recent work on this controversial and perplexing subject

The chapter on local anæsthesia is somewhat disappointing, considerable space is devoted to obtundents, which are recognised to be of limited value, and the detailed account of the preparation of procaine solutions in the surgery could well give place to further information about lignocaine More space, too, could have been given to discussing the advantages and disadvantages of the now almost ubiquitous "cartridge" syringe, especially since it is in regular use by the students at the authors' own hospital Mercurochrome is advocated as an oral antiseptic, but the general opinion is that aqueous solutions are useless, and solutions in alcohol or in acetone are no more nor less effective than the solvents alone

Most of the many illustrations really help to clarify points in the text, and the radiographs are reasonably well reproduced, with the exception of that showing the normal mouth

Another edition of this valuable book will undoubtedly be called for fairly soon, and the opportunity could perhaps be taken to remove those parts of the text that are becoming of less immediate interest to students and dental surgeons today

---

Diseases of the Nervous System (5th ed London Oxford University Press 1955 Pp 996 55s)—To the students' chagrin, successive editions of textbooks tend to get bigger, but, despite the addition of much fresh material, the new edition of Sir Russell Brain's book is a few pages shorter than its predecessors There is new material on cervical spondylosis, the Coxsackie viruses, inclusion body encephalitis, acute hæmorrhagic leucoencephalitis, toxoplasmosis, polymyositis, and neuropathy and myopathy associated with carcinoma, and Sir Russell has added a section on consciousness and unconsciousness to the chapter on the psychological aspects of neurology The treatment of meningitis has been brought up to date with the latest advances in chemotherapy, and recent developments in the treatment of poliomyelitis and lead poisoning are discussed Comprehensiveness and clarity have made Sir Russell's book a firm favourite alike with students, with practitioners, and with neurologists

TABLE IV—BARBITURATE ESTIMATIONS IN BARBITONE POISONING (CASE 16)

Hr after dose	Blood-barbitone (mg per 100 ml)	Urine		
		Volume (ml)	Barbitone content (mg per 100 ml)	Barbitone excretion (mg)
13	41 1			
16½	45 3			
22	49 5

107	27 9	290	117	339
108	Died			
			Total	3 43 g

Ultraviolet spectrophotometric analysis of blood is a rapid and reliable test for the presence of barbiturate, but the significance of a blood estimation depends on the type of barbiturate ingested The long-acting barbiturates are mostly excreted in the urine unchanged (Lous 1954a), and this is reflected in the relatively slow rate of fall of blood-levels The short acting barbiturates are metabolised more rapidly and undergo not only oxidation of their alkyl side chains, but also fission of the pyrimidine ring (Maynert 1952a, b, and c) This is reflected in the more rapid fall of blood-barbiturate levels Those metabolites with an intact pyrimidine ring give positive results with cobalt salts and with most ultraviolet spectrophotometric tests (Maynert 1952c)

When the barbiturate has been identified, or at least classified, the blood-level is a good index of the severity of the poisoning, and may be used to distinguish between medicinal and toxic doses

Lous (1954b) reported that patients given phenobarbitone in doses of up to 400 mg per day had blood levels of up to 6 mg per 100 ml Other workers (Fisher et al. 1948, Goldbaum 1948, Lauritzen 1952, Lous 1954a) have reported blood-barbiturate levels of 0 4–4 mg per 100 ml after medicinal doses, the long acting drugs producing higher blood-levels than the short-acting ones

In acute barbiturate poisoning blood-levels are usually much higher than those found after medicinal doses Several workers (Fisher et al 1948, Goldbaum 1948, Helldorf et al 1949, Nillson 1951, Kyle et al 1953, Wright and Johns 1953, Lous 1954c, Sunshine and Hackett 1954, Wright 1955) have reported blood-levels after acute poisoning, but since different analytical methods were used, and results were often expressed as the unnamed barbiturate or as the acid or sodium salt, such figures may not be comparable From the results given in the present paper it is concluded that blood-levels of 9 mg per 100 ml of long acting, 6 mg per 100 ml of intermediate, and 4 mg per 100 ml of short acting barbiturates indicate severe poisoning These figures, and those at which patients return to consciousness, accord with those of other workers, and are of practical value in that it is now possible to assess the prognosis of an unconscious patient, to have some objective measure of the depth of unconsciousness and to observe the effect of treatment on the blood-level With the data given in this paper useful predictions of the time of return of consciousness can often be made, but it must be remembered that patients may show individual variations or develop tolerance to the drug after prolonged dosage

Blood barbiturate levels previously reported by other workers in fatal cases vary widely (table VI) In some instances this may be due to the presence of other drugs Fisher (1949) suggested that alcohol may exert a synergistic effect and from our results (cases 55 and 59) it is possible that salicylate and paraldehyde have a similar action When assessing fatal blood barbiturate levels it is essential to distinguish between patients found dead, and those who died later in hospital, when complications, such as pneumonia or uremia, may have developed Published reports suggest that the majority of patients who had ingested fatal doses of the long-acting barbiturates died in hospital, whereas those who had taken short-acting ones were more often found dead It will be observed from table VI that blood-barbiturate levels of some patients who recovered were higher than those of patients who died For example, our case 16 remained alive for 4 days with a blood-level higher than that previously recorded for any living patient It is therefore apparent that the fatal blood-level of a given barbiturate cannot be stated, but we may conclude that the following blood-levels are compatible with death from barbiturate poisoning

Long acting barbiturates more than 10 mg per 100 ml
Intermediate-acting barbiturates more than 7 mg per 100 ml
Short-acting barbiturates more than 3 mg per 100 ml

We agree, however, with Fisher (1949) that the finding of these blood-levels does not constitute prima facie evidence of death from barbiturate poisoning

TABLE VI—REPORTED BLOOD BARBITURATE LEVELS

Barbiturate	Blood-barbiturate (mg per 100 ml)		
	Found dead	Died in hospital	Recovered (highest figures)
Phenobarbitone	8	9–40	21 (Lous 1954c)
Barbitone		10–53	20 6 (Fisher et al 1948)
Butobarbitone	1–7		7 7 (this investigation)
Amylobarbitone	3–17	1–2 5	8 6 (Sunshine and Hackett 1954)
Tuinal		4	5 0 (this investigation)
Cyclobarbitone	12		4 5 (this investigation)
Quinalbarbitone	2–7		5 0 (Sunshine and Hackett 1954)
Pentobarbitone	1–58		6 1 (this investigation)

TABLE V—BARBITURATE LEVELS IN NECROPSY MATERIAL

Case no	Age (yr)	Ingested	Blood	C S.F	Urine	Kidney	Liver	Stomach contents	Intestinal contents	Notes
			mg per 100 ml			mg per 100 g		Total (g)		
51	64	Phenobarbitone			Tr *			6 1*	Tr *	Found dead
52		Butobarbitone			22*	Tr *	Tr *	Nil*	0 02*	Found dead
53	50	Amylobarbitone	6 8	~1	4	—	16	3 1	0 57	Found dead
54	45	Amylobarbitone	7 8					0 88*	0 16*	Found dead
55	65	Amylobarbitone – salicylate	>2 5		20	—	5 2	1*	Nil*	Stomach washout 1 hr before death Salicylate present in urine post mortem
56	42	Tuinal	4 9	2 8	5 6	10 1	12 2	0 07	0 37	Found dead
57	45	Quinalbarbitone				21*	2*	0 13*	0 04*	Found dead
58	54	Pentobarbitone	9 0	~5	9 7		98	←17 5→		Died 4 hr after dose
59	39	Pentobarbitone	24 1	3 3	2 2			0 34	0 71	Found dead
60	60	1 8 g pentobarbitone – 340 ml paraldehyde	0 9	0 3	Nil	Nil	Nil	0 43		Found dead Blood-paraldehyde 36 mg per 100 ml

*Figures obtained by weighing after Stas Otto extraction, and barbiturate detected by the reaction with cobalt salts
The remaining results were obtained by spectrophotometric methods

ALEVAIRE

Trade mark

an aerosol solution for excessive bronchopulmonary secretions

TO LOWER SURFACE TENSION and liquefy mucopurulent secretions, 'Alevaire' contains a new detergent in alkaline solution for use alone or as a vehicle for aerosol therapy with antibiotics and bronchodilators It is non-toxic and non-irritant

This preparation is indicated in a variety of diseases and conditions of the lungs accompanied by thickened or excessive bronchopulmonary secretions and in some cases of neonatal asphyxia and bronchiolitis* it has proved life-saving

APPLICATION must be through a nebuliser which will deliver a fine, dry mist when attached to a suitable air compressor or oxygen supply tank, as particle size is of considerable importance

Details of 'Alevaire' and its application are available on request, in a leaflet which also illustrates suitable apparatus

*Lancet, 1954, i, 1011

London Hospital Catgut

A CONTRIBUTION TO SURGICAL HISTORY

LONDON HOSPITAL CATGUT is a product of British scientific research and British labour It fulfils and exceeds all standards laid down by B P It is manufactured under licence from the Ministry of Health

YOU CAN HAVE ABSOLUTE CONFIDENCE IN **LHC**

Sizes 2/0, 0 and 1 are recommended for general surgery, because finer gauges mean less scar tissue and quicker healing.

from nineteen to seventy hours after the second operation The administration of cortisone was started three days before the second operation (the dosage is shown in the figure) The right adrenal gland weighed 4 5 g and the left 3 5 g , on histological examination both appeared normal, and malignant tissue was not found in either gland At first the patient made satisfactory progress, the mammary ulcer began to diminish, and within three weeks of the second operation she was getting out of bed

Terminal course—Pressure necrosis in both buttocks and necrosis of the skin of the left calf over the internal saphenous vein subsequently led to sloughing of the skin and infection The ulcer on the chest wall began to increase in size and depth, and the patient died of bacterial *toxæmia* six weeks after the second operation

Necropsy findings—The carcinoma was confined to the chest wall, and the histological appearance of this tumour still closely resembled that of the original specimen—an anaplastic adenocarcinoma with much necrosis

Intake of Food and Fluid

The patient was encouraged to consume as much food and fluid as she could but was not given a constant intake of either food or minerals , the intakes of protein and calories were deficient throughout the period of study, the daily nitrogen intake seldom exceeding 4 g The intake of potassium was consistently larger than that of sodium, but both were less than the normal minimum The intravenous administration of fluid was limited after the first operation to a short infusion of 5% glucose solution as long as there was anxiety about maintaining the blood pressure After the second operation an infusion of 5% glucose solution was maintained for ninety hours to allow of the administration of noradrenaline and was supplemented by 900 ml of 0 9% saline solution

Findings in Urine

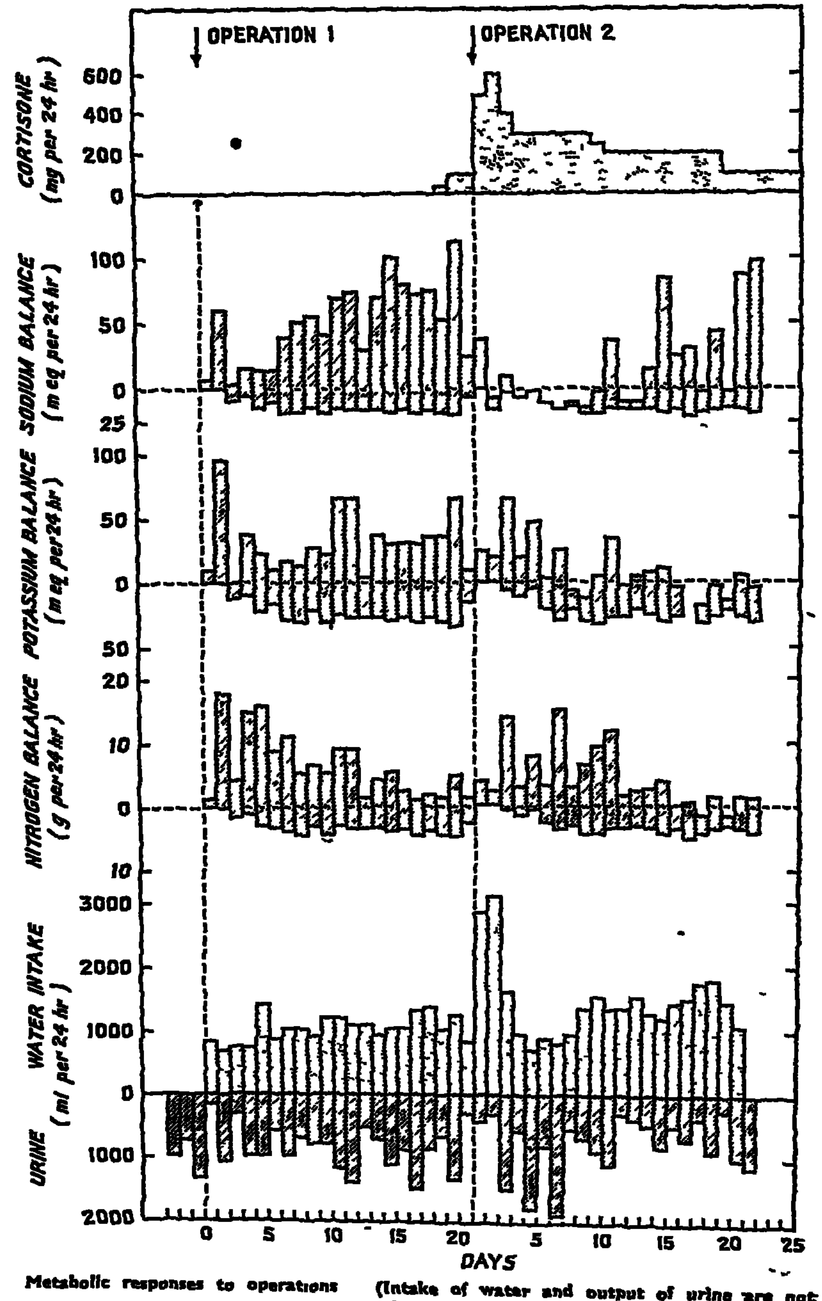
Volume—During the first ten days after the first operation the water intake was equal to the volume of urine, but in the second ten days exceeded the volume of urine by 2 0 litres , after the second operation the water intake exceeded the volume of urine by 5 litres in the first ten days and by 9 2 litres in the second ten days During the first two days after the second operation the water intake was 5 4 litres but the volume of urine only 760 ml Over the next five days the water intake was 4 96 litres and the volume of urine 6 41 litres Thus, after a delay of forty eight hours, there was a large maintained diuresis while the daily dosage of cortisone was 300 mg or more

Specific gravity—After the first operation the specific gravity of the urine remained steadily above 1 018 for three days and thereafter fell below this in only a few six-hour periods—a response which was similar to, but less severe than, that which is usual after operations such as partial gastrectomy (my unpublished observations) After the second operation the specific gravity of the urine fell below 1 012 on the third day and remained below this level for six days and then rose and remained at or above 1 016 from the ninth to the sixteenth day, when it again fell below 1 012

Composition—The changes in composition of the urine (see figure) indicate that, although the metabolic responses to the two operations were in some respects similar, there were also striking differences The total loss of nitrogen was only about half as great after the second operation, and of potassium only a quarter as great, as after the first operation The large negative balance of sodium during the first ten days after the first operation gave place to a small positive balance over the same period after the second operation Sodium conservation after the first operation was within the range to be expected after such an operation, but the later urinary loss of sodium was unexpectedly large After the second operation the sodium conservation was almost complete for thirteen days The potassium sodium ratio of the urine was inverted after both operations , but, whereas it reached a peak of only 1 6 on the second day and was inverted for six days after the first operation, so complete was sodium conservation after the second operation that there was a peak of 50 on the fifth day and the ratio was inverted for thirteen days

Discussion

After total adrenalectomy in animals a normal response to injury appears to depend on the administration of a sufficient quantity of adrenal cortical hormone Ingle et al (1947) showed that, in adrenalectomised rats, after fracture of a tibia the increased urinary excretion of nitrogen, indicating increased katabolism of tissue protein depended on the administration of adrenal



Metabolic responses to operations (Intake of water and output of urine are not expressed as a balance) derivatives was then undertaken.[3-5] Non-sulphonamide thiodiazoles have no hypoglycæmic action, but several compounds of the *p-amino-benzene-sulphonamido-thiodiazole* group lower the blood-sugar in animals. The tertiary butyl and isobutyl derivatives are the most active; then, in decreasing order of activity, follow the butyl, amyl, isoamyl, propyl, and isopropyl derivatives. The ethyl and methyl derivatives are inactive in this respect. Recently another sulphonamide compound, sulphanilyl-*n*-butylurea, has been found to have a similar effect on the blood-sugar level.[6 7] This compound has been more fully investigated in man. After a dose of 2 g. a maximum concentration of free sulphonamide of about 7.5 mg. per 100 ml. of blood is reached in three hours, and there is a considerable fall in the blood-sugar level, which returns to normal in about six hours. The hypoglycæmia can be corrected by giving glucose. With this background information, it was a natural step to ascertain the effect of this substance in diabetic patients.

In one clinical trial[8] sulphanilyl-*n*-butylurea was given to 82 patients with diabetes mellitus of varying duration and severity. The sulphonamide was given after a preliminary period of observation, usually 2.5 g. on the first day, 1.5 g. on the second, and thereafter 1 g. daily. The best results were seen in elderly diabetics. In one group of 28 patients, aged 49 to 77, who had received inadequate or no previous treatment, all but 3 responded well to the drug without the addition of insulin. The glycosuria, by which about 100 g. of sugar had been lost daily, disappeared within a few days and at the same time the blood-sugar fell from fasting values of above 300 mg. to less than 150 mg. per 100 ml. and remained below 200 mg. throughout the day. The renal threshold for glucose did not change. Treatment with sulphonamide was substituted in a second group of 38 patients, aged 41 to 77, who had been previously stabilised on insulin. In 28 it was possible to continue treatment without any insulin. The most favourable results were seen in those with diabetes of recent onset; the response was less satisfactory if previous treatment with insulin had been given for more than a year or two. Further observations in the older patients show that the drug acts gradually and has a long-lasting effect. It is suggested that either intermittent massive therapy or long-continued treatment with small maintenance doses should be given. There is no evidence of the development of tolerance. Fewer observations have been reported in younger diabetics,[6 8] and the results have not been so successful, even where higher doses were given. In most of the younger patients the drug had little effect on blood-sugar levels, but in a few it enabled the dose of insulin to be reduced. In the presence of acidosis there was a poor response, and the substance is clearly unsuitable for use in emergencies. Apart from occasional skin rashes few undesirable side-effects have been reported. As the sulphonamide in its acetylated form is relatively soluble in an acid pH range, there is little danger of crystalluria.

The way in which these compounds work arouses much interest. LOUBATIÈRES[3 5] originally suggested that the β-cells of the islets of Langerhans are stimulated to secrete insulin—a view compatible with the complete lack of action after total pancreatectomy. More recently, evidence has been produced that the primary action is on the α-cells, which are thought to be the site of production of the hyperglycæmic polypeptide known as glucagon.[9] Histological studies in the dog, rat, and rabbit have shown that the α-cells are damaged or destroyed after administration of these sulphonamides[10]; and in one diabetic patient who had received this treatment and who died in uræmic coma, no α-cells were found in the pancreas examined immediately after death.[6] Glucagon is considered by some to play a part in the normal regulation of the blood-sugar level and to act in some respects as an antagonist of insulin. In alloxan diabetes the β-cells are damaged but the hyperglycæmia can be controlled by administration of either *p*-amino-benzene-sulphonamido-thiodiazole or sulphanilyl-*n*-butylurea,[5 7] which destroys the α-cells and presumably thus restores the equilibrium. LOUBATIÈRES and his colleagues[11] now suggest that the sulphonamide not only damages the α-cells but also stimulates the formation of new β-cells. But CHEN et al.,[12] investigating the action of a closely allied compound, sulphanilamido-cyclopropylthiazole, found that in normal rabbits it consistently caused hypoglycæmia, although in alloxan-diabetic rabbits it produced a conspicuous rise in blood-sugar. With the other compounds, a transient hyperglycæmia has sometimes been noted before the fall in blood-sugar. In human diabetes it has been suggested that insulin sensitivity or resistance may be associated with the activity of the α-cells, but this has not yet been fully established.

So far the evidence is insufficient for any definite conclusion about the pharmacological action of these compounds. They clearly open up a new approach to the study of carbohydrate metabolism and diabetes mellitus. The preliminary reports suggest that they may be useful in the oral treatment of elderly diabetics but not of young or acidotic patients. Further carefully planned clinical trials may determine the place of these sulphonamide compounds in the management of diabetes, and we hope that the trials will be completed before these powerful substances become widely available.

Precocious Immunity

IN the classical sense immunity to an infection or toxin depends upon the presence of circulating antibodies. There are, however, circumstances in which some protection is conferred when the presence of antibodies can be excluded. Interference phenomena of this kind are seen in certain virus diseases. Of course, in the case of some viruses the presence of circulating antibodies can be detected and passive immunity can be transferred by serum from convalescent patients; but in other virus diseases the immunity appears to be due to exclusion effects, and after an initial acute infection a permanent symbiosis

the insertion of a soap paste into the cervix; and another patient, a trained nurse, had passed an instrument into her uterus. The other 4 patients refused to disclose details of their abortions.

Case-reports

Case 1.—A woman, aged 38, gave herself a vaginal douche in the 4th month of pregnancy, 14 days before admission to Hammersmith Hospital on Oct. 15, 1947. Vaginal bleeding, vomiting, and oliguria developed, but she had no medical attention until admission, when the products of conception were passed spontaneously. She had passed a very small quantity of dark urine for several days after the onset of vaginal bleeding.

On admission she was pale and drowsy and was vomiting. She was already in the early diuretic phase of acute tubular necrosis, passing large quantities of dilute urine.

Treatment and progress.—She was given an oral Borst diet and her water and salt balances were maintained. She made a satisfactory recovery and was in good health 2 years later, although she had diminished renal function and mild hypertension.

Case 2.—A widow, a trained nurse aged 27, passed an instrument into her uterus on March 25, 1948, and aborted that day. She was admitted to hospital next day because of anuria and jaundice. She was given penicillin on account of fever, and intravenous feeding. She was transferred to Hammersmith Hospital on April 1.

On admission she was pale but not jaundiced; she had facial œdema and epistaxis and she was vomiting. She had a raised venous pressure and a collapsing pulse. There were basal crepitations in both lungs.

Treatment and progress.—The patient was given a protein-free diet, water and salt balance, and blood-transfusion. She was treated twice by dialysis with an artificial kidney, but she died from pyæmia on April 9.

Necropsy showed acute tubular necrosis of both proximal and distal tubules with eosinophil casts in the distal tubules. Acute endometritis and multiple pulmonary abscesses were also present.

Case 3.—A woman aged 27, aborted on April 12, 1948, when 22 weeks pregnant; details of the abortion were not disclosed. She had been anuric from the time of the abortion, and had been admitted to hospital, where she was treated with forced fluids, potassium citrate, and intravenous sodium sulphate. On April 16 she was given a high spinal anæsthetic, and the next day her right kidney was decapsulated. On April 18 she was transferred to Hammersmith Hospital.

On admission she was pale and drowsy, and had a high venous pressure in her neck and œdema of her legs. She was treated with an oral Borst diet, water and salt balance, and dialysis (artificial kidney) on the 5th and 13th days of illness. She made a good recovery.

Case 4.—A woman, aged 24, gave herself an intra-uterine douche of soapy water on Aug. 28, 1948, with the immediate onset of shock, vomiting, and abdominal pain. She was admitted to hospital that day and delivered of an immature fœtus. She was given intravenous fluids and penicillin, and on Aug. 30 high spinal anæsthesia was induced.

She was transferred to Hammersmith Hospital on Aug. 31 and an intragastric drip-feeding régime (Bull et al. 1949) was instituted. She was severely ill in the early diuretic phase, but she eventually made a good recovery.

Case 5.—A woman, aged 20, had a criminal abortion on Oct. 20, 1948, and was subsequently admitted to hospital with uterine sepsis, peritonitis, and anuria. She had blood-transfusion, intravenous fluids, and gastric suction. Uræmic fits developed on Oct. 26, and she was transferred to Hammersmith Hospital three days later.

On admission she was comatose, acidotic, grossly œdematous, and moribund. She died that day before dialysis could be performed.

Necropsy showed acute tubular necrosis of the kidneys.

Case 6.—A woman, aged 27, gave herself a douche of soapy water on Nov. 23, 1948. Within 24 hours she aborted and became oliguric and began vomiting, but she was not admitted to hospital until Dec. 1, when she was given a blood-transfusion for anæmia and kept in salt and water balance. She was transferred to Hammersmith Hospital three days later, when the intragastric drip-feeding régime was started; this was continued for 19 days. Although she was severely ill on admission, she made a good recovery.

Case 7.—A girl aged 16 gave herself an intra-uterine douche of soapy water on Nov. 30, 1948. She was admitted to hospital that day, and her uterus was evacuated and penicillin given. Blood-transfusion for anæmia was started after several days of anuria, and she was given forced fluids and mercurial diuretics without effect. She was transferred to Hammersmith Hospital on Dec. 9, when intragastric drip feeding was started; this was continued for 13 days. She made a satisfactory recovery.

Case 8.—A girl aged 17 had an intra-uterine douche of soapy water and was admitted to hospital the following day with pelvic peritonitis and anuria. There was spontaneous delivery of the fœtus and the placenta was removed digitally. Blood-transfusion was given, and the intragastric drip-feeding régime started. She had a spontaneous diuresis with fall of blood-urea level to 80 mg. per 100 ml. and evidence of recovery of tubular function, but on the 12th day of her illness she showed signs of generalised peritonitis, and she died on the 15th day.

Necropsy showed acute tubular necrosis of the kidneys.

Case 9.—A married woman, aged 37, pregnant for the 5th time, gave herself an intra-uterine douche with soapy water and 'Dettol' on June 18, 1950. This was followed by vaginal bleeding, backache, headache, and vomiting. She was admitted to hospital on June 27 as a case of incomplete septic abortion. On July 3 she underwent dilatation and curettage, and blood-transfusion was given for anæmia (Hb 48%). On July 7 she became drowsy and began having epileptic fits; she had passed urine only about once daily for the previous few days. Her blood-pressure was 176/112 mm. Hg and blood-urea 515 mg. per 100 ml. During the next few days she received intragastric drip-feeding with sugar, fat, and water only; no allowance was made for electrolyte loss in the urine, although her diuresis was steadily increasing. She entered a second phase of oliguria and finally became anuric [illegible] another rise in the blood-urea level, and a fall in blood-pressure due to sodium depletion. She was transferred to Hammersmith Hospital on July 1[illegible].

On admission she was pale and had [illegible] and a dry tongue. Pulse-rate 1[illegible] per minute; [illegible] 80/65 mm. Hg; [illegible] Chvostek's sign; [illegible] muscular weakness and was [illegible] irrational. The plasma [illegible] fell to normal (1·027) when she was given [illegible] chloride and sodium lactate with glucose. [illegible] depletion had been corrected her blood-pressure [illegible] and her blood-urea to fall and she began to pass [illegible]. After this temporary improvement [illegible] developed on July 2[illegible], and [illegible] finally coma, serum-potassium level [illegible] per litre, and the characteristic electrocardiographic [illegible] were present. Despite intravenous [illegible] she died on July 21.

Necropsy showed acute tubular necrosis.

Case 10.—A woman aged 2[illegible], had an abortion induced on [illegible], 1950, but she did not disclose the method used. She was admitted to hospital that day and spontaneous delivery of the fœtus followed with manual removal of the placenta. Blood-transfusion was given for shock. She was oliguric from the time of the abortion. She was transferred to Hammersmith Hospital in the late oliguric phase, and the intragastric drip-feeding régime was continued. She made a good recovery.

Case 11.—A woman, aged 21, aborted on Oct. 20, 1951, by a method not disclosed. She was admitted to hospital, but because of anuria was transferred to Hammersmith Hospital next day. Intragastric drip-feeding was started, but owing to continued vomiting this was changed to intravenous infusion of 2[illegible]% glucose given by 'Polythene' tubing into the superior vena cava. She made a good recovery.

Case 12.—A woman of unknown age was first seen in a nursing-home where a therapeutic abortion had been carried derivatives was then undertaken.[3–5] Non-sulphonamide thiodiazoles have no hypoglycæmic action, but several compounds of the *p*-amino-benzene-sulphonamido-thiodiazole group lower the blood-sugar in animals. The tertiary butyl and *iso*butyl derivatives are the most active; then, in decreasing order of activity, follow the butyl, amyl, isoamyl, propyl, and isopropyl derivatives. The ethyl and methyl derivatives are inactive in this respect. Recently another sulphonamide compound, sulphanilyl-*n*-butylurea, has been found to have a similar effect on the blood-sugar level.[6 7] This compound has been more fully investigated in man. After a dose of 2 g. a maximum concentration of free sulphonamide of about 7.5 mg. per 100 ml. of blood is reached in three hours, and there is a considerable fall in the blood-sugar level, which returns to normal in about six hours. The hypoglycæmia can be corrected by giving glucose. With this background information, it was a natural step to ascertain the effect of this substance in diabetic patients.

In one clinical trial[8] sulphanilyl-*n*-butylurea was given to 82 patients with diabetes mellitus of varying duration and severity. The sulphonamide was given after a preliminary period of observation, usually 2.5 g. on the first day, 1.5 g. on the second, and thereafter 1 g. daily. The best results were seen in elderly diabetics. In one group of 28 patients, aged 49 to 77, who had received inadequate or no previous treatment, all but 3 responded well to the drug without the addition of insulin. The glycosuria, by which about 100 g. of sugar had been lost daily, disappeared within a few days and at the same time the blood-sugar fell from fasting values of above 300 mg. to less than 150 mg. per 100 ml. and remained below 200 mg. throughout the day. The renal threshold for glucose did not change. Treatment with sulphonamide was substituted in a second group of 38 patients, aged 41 to 77, who had been previously stabilised on insulin. In 28 it was possible to continue treatment without any insulin. The most favourable results were seen in those with diabetes of recent onset: the response was less satisfactory if previous treatment with insulin had been given for more than a year or two. Further observations in the older patients show that the drug acts gradually and has a long-lasting effect. It is suggested that either intermittent massive therapy or long-continued treatment with small maintenance doses should be given. There is no evidence of the development of tolerance. Fewer observations have been reported in younger diabetics,[6 8] and the results have not been so successful, even where higher doses were given. In most of the younger patients the drug had little effect on blood-sugar levels, but in a few it enabled the dose of insulin to be reduced. In the presence of acidosis there was a poor response, and the substance is clearly unsuitable for use in emergencies. Apart from occasional skin rashes few undesirable side-effects have been reported. As the sulphonamide in its acetylated form is relatively soluble in an acid pH range, there is little danger of crystalluria.

The way in which these compounds work arouses much interest. LOUBATIÈRES[2 3 5] originally suggested that the β-cells of the islets of Langerhans are stimulated to secrete insulin—a view compatible with the complete lack of action after total pancreatectomy. More recently, evidence has been produced that the primary action is on the α-cells, which are thought to be the site of production of the hyperglycæmic polypeptide known as glucagon.[9] Histological studies in the dog, rat, and rabbit have shown that the α cells are damaged or destroyed after administration of these sulphonamides,[10] and in one diabetic patient who had received this treatment and who died in uræmic coma, no α-cells were found in the pancreas examined immediately after death.[6] Glucagon is considered by some to play a part in the normal regulation of the blood-sugar level and to act in some respects as an antagonist of insulin. In alloxan diabetes the β cells are damaged but the hyperglycæmia can be controlled by administration of either *p*-amino-benzene-sulphonamido-thiodiazole or sulphanilyl-*n*-butylurea,[5 7] which destroys the α-cells and presumably thus restores the equilibrium. LOUBATIÈRES and his colleagues[11] now suggest that the sulphonamide not only damages the α-cells but also stimulates the formation of new β cells. But CHEN et al.,[12] investigating the action of a closely allied compound, sulphanilamido cyclopropylthiazole, found that in normal rabbits it consistently caused hypoglycæmia, although in alloxan-diabetic rabbits it produced a conspicuous rise in blood-sugar. With the other compounds, a transient hyperglycæmia has sometimes been noted before the fall in blood sugar. In human diabetes it has been suggested that insulin sensitivity or resistance may be associated with the activity of the α-cells, but this has not yet been fully established.

So far the evidence is insufficient for any definite conclusion about the pharmacological action of these compounds. They clearly open up a new approach to the study of carbohydrate metabolism and diabetes mellitus. The preliminary reports suggest that they may be useful in the oral treatment of elderly diabetics but not of young or acidotic patients. Further carefully planned clinical trials may determine the place of these sulphonamide compounds in the management of diabetes, and we hope that the trials will be completed before these powerful substances become widely available.

Precocious Immunity

IN the classical sense immunity to an infection or toxin depends upon the presence of circulating antibodies. There are, however, circumstances in which some protection is conferred when the presence of antibodies can be excluded. Interference phenomena of this kind are seen in certain virus diseases. Of course, in the case of some viruses the presence of circulating antibodies can be detected and passive immunity can be transferred by serum from convalescent patients; but in other virus diseases the immunity appears to be due to exclusion effects, and after an initial acute infection a permanent symbiosis

the insertion of a soap paste into the cervix, and another patient, a trained nurse, had passed an instrument into her uterus The other 4 patients refused to disclose details of their abortions

Case-reports

Case 1 —A woman, aged 38, gave herself a vaginal douche in the 4th month of pregnancy, 14 days before *admission* to Hammersmith Hospital on Oct 15, 1947 Vaginal bleeding, vomiting, and oliguria developed, but she had no medical attention until admission, when the products of conception were passed spontaneously She had passed a very small quantity of dark urine for several days after the onset of vaginal bleeding

On admission she was pale and drowsy and was vomiting She was already in the early diuretic phase of acute tubular necrosis, passing large quantities of dilute urine

Treatment and progress—She was given an oral Borst diet and her water and salt balances were maintained She made a satisfactory recovery and was in good health 2 years later, although she had diminished renal function and mild hypertension

Case 2 —A widow, a trained nurse aged 27, passed an instrument into her uterus on March 25, 1948, and aborted that day She was admitted to hospital next day because of anuria and jaundice She was given penicillin on account of fever, and intravenous feeding She was transferred to Hammersmith Hospital on April 1

On admission she was pale but not jaundiced, she had facial œdema and epistaxis and she was vomiting She had a raised venous pressure and a collapsing pulse There were basal crepitations in both lungs

Treatment and progress—The patient was given a protein-free diet, water and salt balance, and blood transfusion She was treated twice by dialysis with an artificial kidney, but she died from pyæmia on April 9

Necropsy showed acute tubular necrosis of both proximal and distal tubules with eosinophil casts in the distal tubules Acute endometritis and multiple pulmonary abscesses were also present

Case 3 —A woman, aged 27, aborted on April 12, 1948, when 22 weeks pregnant, details of the abortion were not disclosed She had been anuric from the time of the abortion, and had been admitted to hospital, where she was treated with forced fluids, potassium citrate, and intravenous sodium sulphate On April 16 she was given a high spinal anæsthetic, and the next day her right kidney was decapsulated On April 18 she was transferred to Hammersmith Hospital

On admission she was pale and drowsy, and had a high venous pressure in her neck and œdema of her legs She was treated with an oral Borst diet, water and salt balance, and dialysis (artificial kidney) on the 8th and 13th days of illness She made a good recovery

Case 4 —A woman, aged 24, gave herself an intra uterine douche of soapy water on Aug 28, 1948, with the immediate onset of shock, vomiting, and abdominal pain She was admitted to hospital that day and delivered of an immature fœtus She was given intravenous fluids and penicillin, and on Aug 30 high spinal anæsthesia was induced

She was transferred to Hammersmith Hospital on Aug 31 and an intragastric drip feeding regime (Bull et al 1949) was instituted She was severely ill in the early diuretic phase, but she eventually made a good recovery

Case 5 —A woman, aged 20, had a criminal abortion on Oct 20, 1948, and was subsequently admitted to hospital with uterine sepsis, peritonitis, and anuria She had blood-transfusion, intravenous fluids, and gastric suction Uræmic fits developed on Oct 26, and she was transferred to Hammersmith Hospital three days later

On admission she was comatose, acidotic, grossly œdematous, and moribund She died that day before dialysis could be performed.

Necropsy showed acute tubular necrosis of the kidneys

Case 6 —A woman, aged 27, gave herself a douche of soapy water on Nov 23, 1948 Within 24 hours she aborted and became oliguric and began vomiting, but she was not admitted to hospital until Dec 1, when she was given a blood transfusion for anæmia and kept in salt and water balance She was transferred to Hammersmith Hospital three days later, when the intragastric drip feeding regime was started, this was continued for 19 days Although she was severely ill on admission, she made a good recovery

Case 7 —A girl, aged 16, gave herself an intra uterine douche of soapy water on Nov 30, 1948 She was admitted to hospital that day, and her uterus was evacuated and penicillin given Blood-transfusion for anæmia was started after several days of anuria, and she was treated with forced fluids and mercurial diuretics without effect She was transferred to Hammersmith Hospital on Dec 9, when intragastric drip feeding was started, this was continued for 13 days She made a satisfactory recovery

Case 8 —A girl, aged 17, had an intra uterine douche of soapy water, and was admitted to hospital the following day with pelvic peritonitis and anuria There was spontaneous delivery of the fœtus, and the placenta was removed digitally Blood transfusion was given, and the intragastric drip feeding regime started She had a spontaneous diuresis with fall of blood urea level to 80 mg per 100 ml and evidence of recovery of tubular function, but on the 12th day of her illness she showed signs of generalised peritonitis, and she died on the 15th day

Necropsy showed acute tubular necrosis of the kidneys

Case 9 —A married woman, aged 37, pregnant for the 5th time, gave herself an intra uterine douche with soapy water and 'Dettol' on June 18, 1950 This was followed by vaginal bleeding, backache, headache, and vomiting She was admitted to hospital on June 27 as a case of incomplete septic abortion On July 3 she underwent dilatation and curettage, and blood-transfusion was given for anæmia (Hb 48%) On July 7 she became drowsy and began having epileptic fits, she had passed urine only about once daily for the previous few days Her blood pressure was 176/112 mm Hg and blood-urea 515 mg per 100 ml During the next few days she received intragastric drip feeding with sugar, fat, and water only, no allowance was made for electrolyte loss in the urine although her diuresis was steadily increasing She entered a second phase of oliguria and finally became anuric, there was another rise in the blood urea level, and a fall in blood-pressure due to sodium depletion She was transferred to Hammersmith Hospital on July 15

On examination she was pale and had dry, inelastic skin and a dry tongue Pulse rate 120 per min, blood pressure 80/63 mm Hg, jugular venous pressure not raised, positive Chvostek's sign, right septic parotitis She had general muscular weakness and was slow in thought and action but rational The plasma specific gravity was high (1 035), but it fell to normal (1 027) when she was given intravenous sodium chloride and sodium lactate with glucose When the sodium depletion had been corrected, her blood pressure began to rise and her blood urea to fall, and she began to pass more urine After this temporary improvement potassium depletion developed on July 20, with tremor, muscular weakness and finally coma, serum potassium level fell from 5 1 to 2 8 m eq per litre, and the characteristic electrocardiographic changes were present Despite intravenous potassium therapy she died on July 21

Necropsy showed acute tubular necrosis

Case 10 —A woman, aged 32, had an abortion on Aug 18, 1950, but she did not disclose the method used She was admitted to hospital that day and spontaneous delivery of the fœtus followed with manual removal of the placenta Blood-transfusion was given for shock She was oliguric from the time of the abortion. She was transferred to Hammersmith Hospital in the late diuretic phase, and the intragastric drip-feeding regime was instituted She made a good recovery

Case 11 —A woman, aged 21, aborted on Oct 20, 1951, by a method not disclosed She was admitted to hospital, but because of anuria was transferred to Hammersmith Hospital next day Intragastric drip feeding was started, but owing to continued vomiting this was changed to intravenous infusion of 20% glucose solution by 'Polythene' tubing into the superior vena cava She made a good recovery

Case 12 —A woman of unknown age was first seen in a nursing home where a therapeutic abortion had been carried sac itself are *not very helpful* But the fœtal mucosæ, especially apparently that of the vagina, provide sufficient suitable cells

There have *lately* been claims for endocrinological methods of antenatal sexing, but none of them seems to have provided an acceptable degree of accuracy Examination of the amniotic fluid seems to be the answer, and, if the first findings are confirmed, it remains *only* to decide what scientific use the method has It could be a *great satisfier of curiosity, and a social* convenience, but it is very seldom *strictly necessary to the health of* either mother or child to know the baby's sex in advance Indeed, it is easy to picture disastrous results, especially when the examination shows that the *child is of an* unwanted sex The discovery is of great interest, but its thoughtless use could be very harmful The same could be *said of pregnancy tests*, which have *sometimes* been abused, but no-one would deny the value of these tests, or of the number of new and unexpected observations in *related fields to which they have led*

Twins are a complication which is not discussed by Dr James or by Serr et al [6] Perhaps the chances of *confusion are not great*, but the occasional occurrence (not so rare apparently as is generally supposed [10]) of dissimilar twins in one amniotic cavity is a possible trap The frequency of multiple pregnancies in most animals of economic importance will probably reduce the interest of the method to veterinarians

Further interesting news of nuclear sexing by non-histological methods is the confirmation from two sources [11] [12] of Davidson and Smith's [13] method of sexing blood-films by examination of the polymorphs

POLYPOSIS OF THE COLON WITH ADDITIONAL FEATURES

MULTIPLE polyposis of the colon has long been known to be due to a dominant mutant gene with nearly 100% penetrance It has been clearly distinguished from Peutz's syndrome, in which other parts of the gastro-intestinal tract (stomach and small intestine) are involved Dukes [14] has lately given a good account of English families with multiple polyposis

A distinct and true breeding variation of the condition, also probably due to a dominant gene, was described in 1954 by Oldfield,[15] in which the polyposis of the colon was associated with multiple sebaceous cysts But, though only one small family was involved, it is possible, but unlikely, that two separate dominant genes, one for the polyps and one for the cysts, were present and that their association in the same individuals was *fortuitous* Another variant was recorded in the United States by Gardner [16] in which in addition to multiple polyposis there were widely distributed epidermoid cysts, fibromas, and osteomas Here a single dominant gene was clearly responsible Precisely the same condition has now been found in another family [17] It is certain, therefore, that here the association is not fortuitous and that a single pleiotropic gene mutation is responsible or, less probable, two or more closely linked gene mutations

Thus, one condition appears in some families by itself, and apparently the same condition, *with further features* constantly added, crops up in other families This situation has a number of parallels for example, pachyonychia congenita in some *families* is accompanied by follicular keratosis and xerodermia, in some families by teeth erupted at birth, but no skin changes, and in one family by follicular keratosis, xerodermia, erupted teeth, and sebaceous cysts Any explanation of the phenomenon must be speculative It seems unlikely that the resemblance within families and differences between families are due to gene modifiers, since they would not be constant within families Research in lower organisms has shown that much the same pheno-*typic character* may be due to a number of mutations of distinct genes which are nevertheless linked It has been suggested that the genes concerned bring about a *chain reaction* and that mutation of any of these may result in the same main biochemical dysfunction But the side effects of these mutations may well differ and *so add different features to the main condition* In other instances mutations having apparently the same main effect may take place on distinct chromosomes and under such circumstances the side effects might be expected to be even more variable

EPIDEMIC KERATO-CONJUNCTIVITIS

THE suggestion that epidemic kerato conjunctivitis was a virus infection was first made by Wright,[1, 2] who, in his study of an outbreak in Madras, was able to demonstrate what he called inclusions in corneal epithelial scrapings, and this material could be used to transfer the disease from man to man Attempts to isolate any infective agent in culture or by transmission experiments in animals were unsuccessful

In 1941 an epidemic of great economic importance broke out in the shipyard workers of the west coast of the United States and gradually spread through most of the country Working with the scrapings from one of these patients, Sanders [3] claimed to have isolated a virus by intracerebral passage in mice This virus could produce the disease in a human volunteer and was neutralised by convalescent serum from patients with the disease After two or three years the major epidemic wave died down and only sporadic outbreaks were reported, from these the Sanders virus was rarely isolated It is interesting to note that in many of these sporadic outbreaks the common connection between those infected was a visit to an ophthalmologist for some other condition, and on occasion it seemed that an instrument may have been the means of transfer—for example, all patients infected may *have had tonography* performed

During 1951 and 1952 work on the Sanders virus [4, 5] made it clear that it was a variant of the St Louis encephalitis virus, and it was *also shown* that sera from the local epidemics then occurring no longer neutralised the virus [6] In contrast to the experiences in the United States, claims to have *isolated* a virus *similar to the* Sanders virus have been made in Turkey [7] and Japan [8] In both cases the virus caused an encephalitis in mice, and Sezer was able to *adapt his virus to produce* lesions on the chorio allantoic membrane of the chick embryo

Despite the isolation of virus by Sanders and others, *there* was considerable *doubt about the importance* of these agents in the disease Recently the condition has been reinvestigated by two groups of workers—Fowle [9] *and her colleagues* in Canada and Jawetz [10] and his associates in California Both these groups have succeeded in isolating viruses of the A P C *group from their patients* In Canada the virus appeared to be an atypical form of course of illness Despite the institution of intragastric drip-feeding on the 11th day of her illness and the onset of diuresis on the 16th day, she died from pulmonary œdema In case 9, renal failure was recognised too late for effective treatment to be applied

Summary

13 patients had acute renal failure after abortion, procured in most cases by intra-uterine douching with soapy water

In all patients the clinical features and laboratory data, and in the 5 fatal cases the necropsy findings, were those of acute tubular necrosis

Of the 5 deaths 3 were due to infection and 2 to water and electrolyte imbalance Some of these deaths could possibly have been avoided by rational treatment in the early stages

MEDIASTINAL SURGICAL EMPHYSEMA
DUE TO PERFORATED DUODENAL ULCER

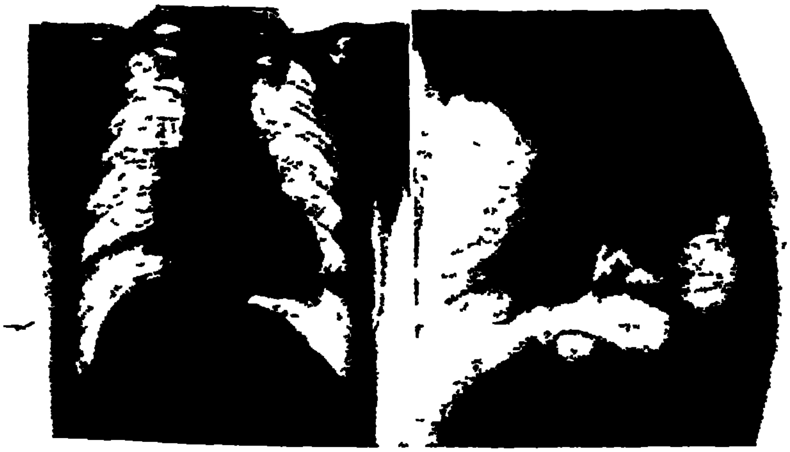
P D O'DONOGHUE
M.B N.Z F.R.C.S
LATE SENIOR SURGICAL REGISTRAR, ST PAUL'S HOSPITAL, LONDON

THE unusual case described here presented an interesting problem in diagnosis

Case-report

A man aged 72, was admitted to hospital seven hours after the sudden onset of severe upper abdominal pain Six hours previously he had noticed in the region of the right shoulder pain which rapidly became severe and persisted He had not vomited. He had long had "digestive troubles" without pain or dysphagia

On examination the patient was dyspnœic, immobile, and ill looking, with cyanosed extremities There was a diffuse surgical emphysema extending from the upper half of the chest-wall over the clavicles and suprasternal notch into the neck as far as the angles of the mandible The pulse was regular and of good volume, blood-pressure 200/100 mm Hg Respiration was rapid and shallow, and the upper abdomen was rigid, intensely distended, and grossly tympanitic



Anteroposterior and lateral radiographs.

Radiography—Anteroposterior and lateral radiographs of the chest and upper abdomen showed wide separation of liver from diaphragm, and mediastinal emphysema extending into the tissues of the neck (see figure)

Operation and Progress—Through a Ryle's tube a large quantity of air was aspirated from the stomach At laparotomy there was severe distension of the peritoneal cavity, which contained a large quantity of free gastric content On the anterior surface of the first part of the duodenum was a small perforation about the size of a pin-head Para-œsophageal herniation of the peritoneum, with intact wall was present The perforation was closed and the peritoneal cavity cleared by suction The wound was closed without drainage Postoperatively the bowel sounds returned on the second day, the emphysema had appreciably diminished by the third day, and finally disappeared on the twelfth day During convalescence there was no suggestion of a "post-operative chest" or of mediastinitis When the patient was seen at follow up six months later his general condition was good, and he was symptom-free

Discussion

Sudden spontaneous epigastric pain with abdominal rigidity, respiratory distress, and subcutaneous emphysema of the neck in an elderly patient is reasonably regarded as pathognomonic of spontaneous rupture of the œsophagus Yet this is uncommon, especially where there has been no previous evidence of an œsophageal lesion In the present case there was little reason to assume the presence of a predisposing œsophageal lesion such as injury, nor was there sudden overdistension by the ingestion of an over-bulky bolus or volume of fluid A trivial and unsuspected injury, however, may sometimes cause a breach in the mucosa producing a "dissecting" lesion (Nanson and Milnes Walker 1953) The patient was not shocked Clinically the likeliest diagnosis was spontaneous rupture of a healthy œsophagus—a disorder diagnosed preoperatively and successfully treated on only a score or so of occasions (most recently in three cases reported by Borrie (1955))

The clinical findings therefore indicated spontaneous œsophageal rupture, but this was not supported by the history There were however adequate grounds for diagnosing perforated peptic ulcer, and this diagnosis was later substantiated by the radiographic findings

The association of perforated duodenal ulcer with mediastinal surgical emphysema must be very rare Mediastinal emphysema is a recognised complication of artificial pneumoperitoneum, but the mechanism is not clear

In the present case air may have escaped into the mediastinum through a small breach in the thin peritoneum of the hiatus pouch, but this was not evident on cursory palpation At all events the radiographs demonstrate continuity of the abdominal and thoracic air. The important factor in this case was the extreme tension within the peritoneal cavity and stomach Gastric contents must have been forced into the lower mediastinum but this gave rise to no untoward reactions during convalescence

There is a good case for routine radiographic examination of the chest and upper abdomen in cases of clinically "obvious" perforated peptic ulcer

I thank Mr N E Stidolph, senior surgeon, Whittington Hospital, under whose care this patient was admitted, for the opportunity of treating and reporting the case

M A, Ph D Camb
OF THE LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE

IT is hard to recapture nearly three years later the mood of public opinion at the time the Guillebaud Committee was appointed There were many who believed that the National Health Service, adventurously launched in *1948*, would founder on the problem of finance The big supplementary estimates required for the service in the early years came as a shock to public opinion There was a widespread impression that the service was "*out of control*" Some ascribed the sharp increase in cost that was believed to have occurred to the boundless potentialities of medical science Others were under the impression that the demands of the aged were *very much greater than those* of younger people and feared the consequences of an ageing population on the bill for medical care Propelled by these and other forces, the cost was expected to soar relentlessly upward

These *apprehensions*, which were *expressed* in Parliament and outside, received support from the writings of Dr Ffrangcon Roberts His book on *The Cost of Health* was widely read and widely quoted Much of it was based on the experience of one teaching hospital

It was in this atmosphere that the Guillebaud Committee was appointed "to review the present and prospective cost of the *National* Health Service, to suggest means, whether by modifications in organization or otherwise, of ensuring the most effective control and efficient use of such Exchequer funds as may be made *available*, *to advise how, in view of the burdens* on the Exchequer, a rising charge upon it can be avoided, while providing for the maintenance of an adequate service, and to make recommendations"

Soon after the committee was set up, Mr Guillebaud asked the National Institute of Economic and Social Research to sponsor the preparation of a memorandum presenting an economic analysis of the costs of the National Health Service This memorandum, which was published this week in a revised form,[1] is summarised below Inevitably, conclusions are stated here without all *the reservations to which they are subject* And many questions discussed in the book are omitted

The cost of the National Health Service that emerges from the Government accounts is *ambiguous* Costs of many *different kinds are added indiscriminately together* in these accounts, the purpose of which is to ensure accountability to Parliament rather than to provide a useful record for economic *purposes* For example, the accumulation of cash and the purchase of herrings by hospital authorities clearly need separate treatment And, for certain purposes, higher remuneration awarded in one year for services performed in earlier years should be allocated to the year when the work was done, rather than to the year when payment was made

The figures which *follow* are derived from a laborious rearrangement of the official records of expenditure (published and unpublished) by the central Government, hospital authorities, executive *committees*, and local authorities Our main concern is with the cost of the National Health Service in terms of current productive resources to public authorities as a group, distinguishing current from capital *costs* so far as the records permit Often exact information was not available and we had to rely on estimates which we made in conjunction with the Ministry of Health The many qualifications to which *our figures* are subject are set out in the book

Current Cost

The current *cost of the National Health* Service falling on public authorities was £371$^{1}/_{2}$ million in 1949-50 In the subsequent years it rose by roughly *£15 million* each year, reaching £430$^{1}/_{2}$ million in 1953-54 This rise of £59 million was the result of a larger increase (£77 million) in gross costs, offset by a saving of £18 million by new or increased charges to beneficiaries

The *proportion of total* national resources (the gross national product) paid for by public authorities *fell* from 3$^{3}/_{4}$% in *1949-50 to* 3$^{1}/_{4}$% in *1953-54* Had the proportion of resources devoted to the service in 1953-54 been *the same as in 1949-50 the* net cost *would have* been £67 million higher

During the period under review there was a considerable general rise in prices We have tried to estimate the effect of *price increases on the cost of the Service*, recalculating expenditures at constant (1948-49) prices The current net cost of the service expressed in "real" terms in this way, was only *£11* million greater in 1953-54 than in 1949-50 Thus, the net *diversion of resources* to the National Health Service since 1949-50 has been of relatively insignificant proportions There was a *rise of nearly 2% in population during the period* under review Allowing for this and for changes in the age structure of the population, the cost *per head* at constant prices was almost the same in 1953-54 as in 1949-50

Trends of *expenditure have been very different* in different parts of the service Between 1949-50 and 1953-54 net current expenditure on the hospital services rose by £71 million, and that on local authority services by £11 million, while expenditure on executive council services fell by £24 million The movement of total health service expenditure thus represented the combined *result of these divergent trends, a fact which needs to* be taken into account in considering future trends

A major part of the rise in hospital expenditure was attributable to rising prices (£41$^{1}/_{2}$ million of the £71 million increase *from 1949-50 to 1953-54)*, but the rise in the net volume of goods and services purchased (£29$^{1}/_{2}$ million at 1948-49 prices) was also substantial The increase in labour services as a whole accounts for three quarters of the increase in resources used in the hospital service at constant prices The categories of staff which increased most were nurses and domestic staff The transfer of consultants from whole time to part time service and the expansion of the domiciliary specialist service contributed to the higher cost of labour services The major part of the increase in goods purchased by the hospital service was "medical goods" (drugs, dressings, equipment, appliances, &c) "Non-medical" purchases increased by only *£4 million* (7%) This increase of 7% was about the same as the increase in average daily occupied beds over the same period

Against this increase in cost have to be set the quantitative facts that the hospitals did more work for a larger national population, more confinements took place in hospital, more services were rendered to general practitioners, more provision was *made for road and industrial* accidents, more people were trained and more research was undertaken All these are quantitative indices of activity, what cannot be assessed is the *changing* work of the hospital as an agent of humanity

The different executive council services show different trends in expenditure While the pharmaceutical service and the general medical service each increased between 1949-50 and 1953-54 by £6 million, expenditure on the dental service fell by £24 million, and that on the *ophthalmic service by £13 million* The rise in the cost of the general medical service was almost entirely due to the increased cost per patient year resulting from the Danckwerts award to general practitioners The rise

A HEADLIGHT FOR GENERAL SURGERY

It is necessary in many operations to see deep into narrow spaces At a certain degree of depth and narrowness this can only be done by means of a light which originates in front of the surgeon's eyes and coincides fairly closely with his line of sight This of course means a headlight and after many attempts I have designed one which satisfies me Its points are

1 Brilliancy sufficient to compete with the intensity of ordinary main operating-lights, so that there is no need to darken the theatre

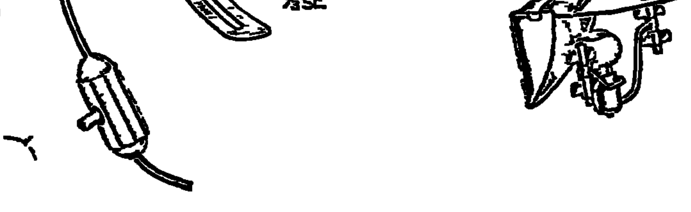
2 An area of illumination intense in the centre, gradually fading out towards the edges This corresponds to the visual consciousness of the surgeon, and is far better than the clear-cut levelly illuminated field I at first tried for Any slight irregularities in the field of light will be found quite unnoticeable when working

3 An approximately parallel beam, which remains without significant change in area or intensity on variations in working distance This can be attained only by a reflector system

4 A beam which coincides with the line of sight closely enough for all ordinary surgical work The slight increase in optical efficiency gained by looking through a hole in the mirror does not compensate for the loss of peripheral vision

5 A frame to hold the bulb which allows focusing accurately and firm fixation when this is arranged

6 An attachment to the head which is easily adjusted and which does not depend on that tight grip across the forehead which causes headache. The slight weight of the light is taken by an overhead band loosely held at either end by a circular one



7 An adjustment for different types of work by a friction joint allowing the only movement necessary—that of up and down in the sagittal plane (Most headlights have absurdly complicated and varied mountings) This can easily be adjusted by a non-sterile assistant

8 A bulb with an opaque-mirror backing over the front two-thirds of the lens This increases the light sent backwards into the mirror and in addition stops glare getting into assistants eyes

9 A shield round the lower part of the mirror to prevent glare into the surgeon's eyes It is possibly the lack of these last two devices which has caused the non-perforated reflector type of light to be little used

10 A battery, cheap and of large capacity, specially adapted to the bulb, it is worn on a belt round the waist with an ordinary commercial switch on the flex so that it can be put into action through the gown The light can, of course, be run off the main by those who do not object to being tethered by a flex

The light is made by Messrs Down Bros of 32, New Cavendish Street, London, W 1, to whom I am indebted for help in working out many details

Reviews of Books

Breast Cancer and its Diagnosis and Treatment

EDWARD F LEWISON, M.D F.A C.S, assistant professor of surgery, Johns Hopkins University School of Medicine Baltimore Williams & Wilkins London Baillière, Tindall, & Cox. 1955 Pp 478 114s

In a foreword, Dr Grantley Taylor admirably sums up the importance of cancer of the breast to the whole problem of malignant disease As he points out, our ideas of malignant disease "derive largely from observations of breast cancer", and "breast cancer was the prototype for the development and perfection of the concept of the radical operation for cancer" The experimental study of heredity in cancer has been chiefly carried out on cancer of the breast in mice Again, cancer of the breast is one of the few forms of cancer which has so far responded to "therapeutic modifications of the hormonal environment" It is no wonder therefore that many people feel that, if the exceedingly tough shell of the cancer problem is broken at the clinical level, it is likely to be through cancer of the breast

This book assembles the known facts, with the emphasis on the tradition of surgery of the Johns Hopkins, and particularly of Halsted Thus, the first chapter gives an interesting account of the history of breast cancer the culmination of which is the development of the operation of radical mastectomy by Halsted And the greater part of the book represents the traditional surgical point of view, given by a surgeon who obviously has extensive knowledge and experience and has given much thought to the practical problems involved

Dr Lewison has taken the lion's share of the work, but he has been helped by eight distinguished colleagues The one British contributor, Mr R S Handley, has written an excellent chapter on the surgical anatomy of the breast, in which he cleverly manages to give a dynamic twist to the subject and to discuss the principles of breast surgery This is the only part of the book in which the question whether the pectoralis major should be sacrificed in radical mastectomy is discussed elsewhere this procedure, the main technical contribution of Halsted to breast-cancer surgery, is unquestioningly accepted The book makes no reference to the classical article by Gray on the lymphatics of the breast, which undermines the traditional pathological arguments in favour of routine removal of the pectoralis major

There is a very detailed account of "classical" radical mastectomy, but in the chapter on hormonal treatment only a bare mention (without any technical operative details) of adrenalectomy, and no discussion of the possible ways of destroying the pituitary influence Diagnostic manœuvres are fully described, and the importance of biopsy is properly stressed The author rightly notes that palpation of the breast should be carried out with the pulps of the fingers

In the case of capital expenditure, the central Government has proved a much sterner master than local authorities and those who directed the voluntary hospitals The population changes estimated for the next twenty-five years give no cause for concern

---

Public Health

POLIOMYELITIS VACCINATION

At a press conference on Jan 19, Mr R H Turton, the Minister of Health, announced that a British variant of the Salk vaccine would be ready for local health authorities to use during May and June of this year Only a limited amount of vaccine would be available, and it would be given free under the National Health Service Mr Turton hoped that between 300,000 and 500,000 children would be vaccinated by the end of June Only children born in the years 1947–54 could be considered for vaccination at present, the scheme was entirely voluntary, and written permission for vaccination from parents or guardians was obligatory No vaccinations would be given between the end of June and November (the poliomyelitis "danger period"), and those children who could not be vaccinated before the end of June would receive priority when more vaccine had been prepared later in the year Each child would have two intramuscular injections of 1 ml of the vaccine with an interval of not less than three weeks between the injections For the time being, only local health authorities would be given supplies of the vaccine, but, when more became available, general practitioners would be given the opportunity of participating in the scheme

Mr Turton said that the British vaccine, which will be the only type used, had been subjected to the most stringent safety tests and was preferable to any made in other countries Asked whether parents might hesitate to have their children vaccinated because of the cases of poliomyelitis during early trials in the United States, he pointed out that, because of improved safety measures, at least 10 million children in the United States and over 1 million in Canada had since been vaccinated without a single mishap, and he was confident that this knowledge would remove any doubts as to the vaccine's safety

Prof S P Bedson, F R S, chairman of the Safety Committee of the Medical Research Council, said that the British vaccine was prepared from three strains of virus, but the highly virulent type I (Mahoney) strain of the Salk vaccine had been replaced by one of lesser virulence, it was planned eventually to replace types II and III with milder strains

Vaccine is being manufactured in the Glaxo and Burroughs Wellcome laboratories Both laboratories have substituted a less virulent strain for the type I used by Salk, and we understand that the Wellcome vaccine will contain attenuated strains of type II and III virus, as used by Sabin

A Ministry of Health circular to county councils and county-borough councils says that the councils should explain the proposals to all parents (or guardians) of children of eligible age in their area and ask them to express their willingness in writing to have their children vaccinated The circular goes on to say that "the selection of children to receive the vaccination from among those whose parents seek it will be made according to a centrally determined plan designed to maintain an even spread throughout the eligible age groups which will be based on the month of birth When the national picture can be studied local health authorities will be informed which months in each age group have been selected and the children whose birthdays are in those months should be vaccinated as and when the vaccine is received by the local health authority"

Influenza in Suffolk

As we briefly reported last week, there has been much influenza-like illness in recent weeks in Suffolk, and influenza-A virus has been identified from 2 cases in Ipswich A doctor in practice in the area has kindly sent us the following account of his experiences of the epidemic

"It began in mid December just as we were in the middle of an epidemic of measles The illness affected all ages and often involved several members of the household The incubation period was from 2 to 3 days The epidemic reached its height in the first week of January and has now practically disappeared

"The onset was acute with headache, generalised pains in the back and limbs, pyrexia, tachycardia, and, within 24 hours, a cough In younger patients the cough appeared to be a manifestation of a tracheitis, in the older people the disease often progressed to acute bronchitis and in the very old bronchopneumonia was fairly common My partners felt that for the bronchopneumonia aureomycin (chlortetracycline) or 'Achromycin' (tetracycline) was the most helpful, but I saw 4 cases in which the response was inadequate and penicillin was successful In the absence of antibiotic treatment the pyrexia lasted for 2 to 3 days, and by the 4th day most patients were much better, but the cough often persisted for a week or 10 days and longer in those who had bronchitis

"About 190 cases were seen among about 10,500 patients Only 1 death was attributable to influenza—in a man of 89 who died within 48 hours of bronchopneumonia In conjunction with the Public Health Laboratory Service we are trying to isolate the virus from garglings and to find antibodies in blood taken from the 10th to 21st day after the beginning of the illness

"On the whole we do not regard this as a big epidemic, and we were rather surprised to learn that the sickness-rate was so high compared with the rest of the country The epidemic is now tailing off and today (Jan 19) only 3 new cases were seen"

Before Our Time

A RELIC OF AN 18TH-CENTURY ISOLATION HOSPITAL

FRANCIS W STEER

F S A

COUNTY ARCHIVIST, EAST AND WEST SUSSEX

IN 1718, on her return from Constantinople, Lady Mary Wortley Montagu began to advocate the practice of inoculation against smallpox Seven condemned criminals were used as guineapigs in 1721, the success of the experiment led to two members of the royal family being inoculated in the following year But the idea of inoculation was to begin with "suspected as unnatural and even impious"[1] Bishops and clergy preached against it, though smallpox had been responsible for 1 out of every 14 deaths in London in 1723 From the journals of St Bartholomew's Hospital[2] we learn that in 1752 "it was resolved that patients taken ill with small-pox be immediately removed into other wards to be kept separate for that purpose", the wards named Job and Lazarus were aptly selected for these isolation blocks

Smallpox was common and devastating in the country as well as in towns, and it was a heavy burden on the poor rate because an outbreak meant expensive nursing charges After the early experiments with inoculation, the disease slackened, particularly in the country districts, but bills among the papers of the overseers of the poor

In common winter infections . . .

'ILOTYCIN' ERYTHROMYCIN

TRADE MARK BRAND

'ILOTYCIN' is rapidly bactericidal to Gram-positive organisms, including staphylococci, streptococci and pneumococci. Orally administered, it gives adequate 2-hour blood levels, is perfectly safe, well tolerated and free from unpleasant side effects.

AVAILABILITY

'Ilotycin' Tablets 100 mg. and 250 mg. Average dose 1 Gm. daily.

'Ilotycin' Paediatric in palatable *liquid form*. Average dose ½ teaspoonful per stone body weight every 6 hours.

Lilly
TRADE MARK

ELI LILLY & COMPANY LIMITED

BASINGSTOKE HANTS

'Eminently suitable for medicinal purposes'

'In view of these analytical and general evidences, this brandy may be described as particularly suitable for medicinal purposes'

See Lancet, July 22, 1899, p. 219

'The evidence both of analysis and taste indicates that the high standard of purity and quality has been maintained and that the brandy is eminently suitable for medicinal purposes'

See Lancet, May 7, 1932, p. 992

make friends with MARTELL

My visit may be the only live contact these remote folk have with the outside world within a week during the cold winter months I have learnt that a doctor's job may be varied On a night call I may find a patient with coronary thrombosis and give morphia But the house is cold and lonely for the old folk who have no outside help, and the kindling of a blazing fire in the hearth brings the patient almost as much comfort as the injection At another house an old lady is panting with asthmatic bronchitis I count out the antispasmodic tablets for her into a saucer, but far more important I supervise the removal of her bed from a bedroom up rickety stairs to the sitting-room on the ground floor It would be worth calculating the digitalis equivalent of this simple manœuvre to the over-burdened heart Yet another woman with involutional melancholia sits there immobile day after day I can do little for her She has had expert treatment But one thing she will let me do—cut her nails

* * *

G P s and M P s alike can hardly wait for the latest number of *Proscribers' Notes* with its detailed account of the recent brilliant investigation by Prof T Cobbleigh and his colleagues [1] at the Widdicombe Research Unit

These workers injected watery solutions of different antibiotics into a series of patients, and (owing to the near-sightedness of Professor Cobbleigh) also into a grey mare The mare hastily went A W O L, but all the patients recovered As water was the only ingredient common to all the injections, the logical inference is that the water was the curative agent

After the injection, the patients were asked, "How do you feel?"

25 % (Group A) replied, "Better"
25 % (Group B) replied, "Worse"
25 % (Group C) replied, "Don't know"
25 % (Group D) replied, "x — — — x x x you x x!"

He—i e, group D—was thereupon withdrawn from the series and sent for a Freudian analysis

When the survivors were confronted with further injections, even a glimpse of the solution in the syringe produced dramatic improvement For example, group B said that he had originally replied "Worse" only because the needle was getting a bit blunt when it was his turn, and group C acquired such an improvement of insight into the extent of his recovery that he reached the front door of the unit before recapture

The final percentage figures, confirmed by UNIVAC, random sampling, and extrapolation of skew-curve deviation—due to the bubbles in Professor Cobbleigh's syringe—prove that antibiotics are unnecessary

This discovery is as timely as it is revolutionary, for, as Professor Cobbleigh emphasised, there is a number of antabiotic addicts in these islands Indeed a suspected fourth one was reported yesterday, but it was found that he was only collecting the little bottles for his children to play with In contrast, there are no cases known of addiction to injections of water

BALLAD OF SMITHFIELD

Twa butchers sat in Smithfield fair,
Bummaree, O Bummaree!
And there they made their moan so sair,
By the bonnie church of Bartholomew

There cam a buyer bold and brave,
Intent, it seems, on ways to save

"*Now sell me meat* of goodly brand,
And place it safely in my hand"

"O robber false, thy haste now stay,
Thou canst not carry it away

"Of trusty porters there's five score,
Ignore them and they'll raise a roar"

He's ta'en the meat in his right hand,
And flouted all the porter band

Foul fa' the hand that takes the meat,
Bummaree, O Bummaree!
And leaves the porters sair to greet,
By the bonnie church of Bartholomew

Letters to the Editor

DOMICILIARY CONSULTATION IN PSYCHIATRIC PRACTICE

SIR,—I am glad that Dr Hopkins now makes it cle (Jan 14) that admission to hospital was advised in 3 of the 5 schizophrenic patients in his series, though this was achieved in only 1

His very full reply to my inquiry emphasises two matters of considerable importance first, the need for agreed clinical criteria that should be fulfilled in order to establish a diagnosis of schizophrenia, and secondly the need for helping people with disabled personalities (whether due to partially remitted schizophrenia, inveterate neurosis, or anomalous deviation of the personality) who are incapable of benefiting by further active treatment, and are not ill enough to require prolonged hospital care but not well enough to stand on their own feet in the community In such cases the accent is often on social rather than strictly medical methods The day hospital that Dr Hopkins mentions is one practical step, certainly in large towns Another possibility is boarding out, which for many years was successful in Scotland and on the Continent but has never found much favour in England and Wales, perhaps because the propaganda which might have led to its effective adoption was in some ways imperfect when it was last propounded in the early 1930s

There is now a third possibility It is surprising how seldom one sees reference, in this context, to the powers of local authorities under Part III of the National Health Service Act A fair analogy would be to compare the kind of crippled personalities that we are discussing with ambulant tuberculous patients who can no longer benefit by inpatient treatment Progressive local authorities make no bones about their duties in respect of such patients, but few of them seem to have taken very active steps about the community care of mentally disabled persons other than ascertained mental defectives It is not easy to suggest exactly what local authorities might do, but at least it would be a beginning if one or two pilot surveys were made, in representative areas, in order to ascertain the numbers of such persons, the extent of their disabilities, their social circumstances, and the prospects of employing them gainfully under supervision, possibly as registered disabled persons Such surveys might justify the experimental establishment of one or two small hostels specifically for the use of patients within this group whose domestic circumstances were such that they could not suitably remain in their own homes, though they need not occupy beds in mental hospitals Such an experiment would be rather differently oriented from the "therapeutic community" type of venture, for it would aim to deal with those who, from the start, have little or no chance of complete rehabilitation

Dr C A H Watts's [1] survey, to which Dr Hopkins refers, is valuable and realistic in showing how this problem affects general practitioners as things are at present But there is more in this problem than clinical attention to individual patients, and I feel sure that general practitioners and psychiatrists together would welcome a more widely informative survey, and, if practicable, more comprehensive help, than any individual can provide

Restriction of Antibiotics ?

AMONG antibiotics, erythromycin has the particular merit that it will often work when others have failed and from time to time we have urged our readers not to blunt this therapeutic weapon by using it for lesser purposes, but to keep it sheathed unless nothing else will save the patient's life The advantages of doing this are plain, but so also are the difficulties, and the New Zealand government have decided that on this subject advice to doctors must now be reinforced by restrictions Because a number of children have died from infections by organisms no longer vulnerable to any antibiotic, they have decreed that, from Feb 1, New Zealand doctors shall be able to get erythromycin only through hospitals and only for the treatment of diseases which do not respond to other remedies This announcement by the minister of health, Mr J R HANAN, will arouse interest in many other countries, for, like the ban on heroin, the action now being taken may be regarded as an interference, by a government, with the doctor's freedom to treat his patients in whatever way he chooses

Looking at it bacteriologically and epidemiologically, there seems everything to be said in favour of the New Zealand decision When penicillin was first made available to civilian hospitals in 1944, in desperately small quantities, its use as a life-saver was one of the spectacular advances of our time Those who had the hard task of allotting the scarce supplies will remember the many painful decisions they had to make, and the early days of penicillin were often darkened by the need to refuse, but they were also lightened by the remarkable efficacy of the drug when it was used in the right way in the right cases In those days of scarcity a few skilled hands achieved excellent results, and there were no mysterious and fatal forms of enteritis and no other complications due to sensitised patients and resistant organisms Now that antibiotics are plentiful, cannot the benefits of the lean years be restored, without their sufferings, by restricting the use of these substances, by common consent ? On purely scientific grounds, it is hard to see why such restriction should not have the desired effect, if it is wisely and firmly applied, for, when an antibiotic is used less widely, the number of bacteria resistant to it diminishes swiftly If the New Zealand plan is to do what is intended, the hospitals, of course, will have to be even more sparing than the general practitioners in their own use of erythromycin, for it is hospitals, not sickrooms in the home, that are the great sources of antibiotic-resistant organisms We hope, therefore, that Mr HANAN has told the hospitals to go very carefully in their own use of erythromycin Provided this vital point is covered, there are very good reasons for keeping one or more antibiotics in reserve for use in the last resort

But how exactly should the restriction be secured ? Some doctors are notably careful in their prescription of antibiotics, and it may be that the proportion who take thought about this has increased as more and more accounts have been published of the dangers of abusing these agents But it is still unfortunately true that the habit of giving antibiotics unwisely and even casually is the cause of much avoidable disability to patients and it would be over-optimistic to suppose that the mere publication of advice is enough to ensure that a drug such as erythromycin is used only when life is in imminent danger It would no doubt be easy to arrange for a suitably qualified group of doctors to meet from time to time to survey the antibiotics in use and to recommend that one or other should be "rested" long enough to restore its full power, but difficulty might well arise as soon as a move was made to give such recommendations the force of law It is possible that the kind of restriction now applied in New Zealand would be found acceptable here because its pattern resembles that already adopted for the distribution of important drugs while they are still scarce, and because it does not in fact embody anything like a complete ban On the other hand, recent happenings have made it seem likely that a regulation on the New Zealand pattern would be resented in this country Thus, paradoxically, it looks as though a course of action which most doctors would acknowledge to be sound scientifically, and necessary for the good of patients, may be neither voluntarily adopted nor tolerated if imposed It is evident that, as a profession, we must try to discover means of bringing to bear upon the interests of all patients, whether known to us by name or not, the kind of wise judgment and resolute action which a good doctor prides himself on giving the patient directly in his charge The New Zealand decision should make us think again about the way in which antibiotics are being used in our own country, and we should also consider from whom, if not from a Government, doctors would accept direction on such subjects

Sulphonamides and Hypoglycæmia

DURING a clinical trial of the chemotherapeutic action of *p*-amino benzene-sulphonamido-isopropyl-thiodiazole, JANBON and his associates[1] noted that this substance produces a fall in the blood sugar level which may be so profound as to lead to hypoglycæmic coma This clinical observation was confirmed by experimental studies in rabbits and dogs[2] Oral or subcutaneous administration to dogs results in hypoglycæmia, the blood-sugar falling to as low as 40 mg per 100 ml within five hours With continued administration, chronic hypoglycæmia develops and may cause irreversible neurological changes similar to those observed after prolonged insulin hypoglycæmia The decrease in blood-sugar is proportional to the concentration of this sulphonamide in the blood, and experimentally, hypoglycæmia is obtained with [illegible] lower doses if the sulphonamide is injected [illegible] into an artery supplying the neck of [illegible] After total removal of the pancreas [illegible] hypoglycæmic action, but it persists [illegible] of the gland is left A stud[illegible] its full complement of nurses of both sexes and a waiting-list

[1] Janbon M, Chaptal J [illegible] *méd* 1942, 21 22

[2] Loubatières A [illegible]

None of us likes empirical treatments We are not enamoured of electroplexy, insulin, or neurosurgery Nevertheless, when employed with discrimination in every orthodox mental hospital, these methods produce remissions or recoveries They are not used for administrative purposes or as methods of restraint The ever *increasing* number of open wards, better atmosphere, and vastly increased freedom extant in such hospitals should be apparent to the meanest intelligence or most careless observer

Finally, no nurse of ours polishes floors Nurses of both sexes, if asked by Dr Hunter, will inform him in no *uncertain* terms that the last two decades have brought them increased dignity, stature, and standing rather than the reverse

We realise that we still have far to travel in the field of psychiatry, and we feel that its interests would best be *subserved* by balanced judgments and *fewer* sweeping assertions on the part of those practitioners in this sphere not immediately connected with mental hospitals

Dr Hunter would be well advised to pay a round of visits to representative mental hospitals wherein we are convinced he will find nursing personnel with erudition and *dignity* equal to his own

INTRAGASTRIC MILK DRIP IN TREATMENT OF UPPER GASTRO-INTESTINAL HÆMORRHAGE

Sir,—Dr Dawson, in his article on the continuous intragastric milk drip in the treatment of upper *gastro* intestinal hæmorrhage (Jan 14), makes critical reference to our observations [3] on the value of the indwelling tube in the management of hæmatemesis Our continued experience of the method, which now extends to 225 patients, has, if anything, increased our confidence in the procedure

The recognition of further gastric hæmorrhage formed *only a small part of the original study of* 105 patients, of equal value, and disregarded by Dr Dawson, has been the information provided as to the site of ulcer by the association of clear aspiration specimens with clinical evidence of continued bleeding, indicating a source of hæmorrhage beyond the pylorus These factors, in conjunction with the gastric secretory patterns observed during and after the acute stages of gastroduodenal hæmorrhage, led to the correct recognition of the pathological cause of the bleeding in a significant proportion of the patients studied We suggest that the complete application of the method might have improved the results obtained, our mortality of 4 8% in 225 unselected patients so investigated comparing favourably with Dr Dawson's series (8 in 100 patients)

We would agree with Dr Dawson that the reappearance or continuance of blood-staining of the gastric contents does not necessarily herald a further massive hæmorrhage, but its presence gives no grounds for complacency, and, with other criteria, will lead to the earlier recognition and treatment of this complication

We believe that a complete regard for all the points ma *in our paper* can do much to stimulate awareness of th diagnostic *problem and* to facilitate its earlier solutio *From our further* experience we see no reason to modif *our original* conclusion that early gastric aspiration a *materially in the management* of hæmatemesis

BREAD

Sir,—Professor McCance and Dr Widdowson concluded their article on Old Thoughts and New Work on *Breads* White and Brown [1] by saying "It is of course always quite possible that little attention will be paid to these experiments of ours " I have just re read their original report,[2] which confirms the conclusion I first came *to that the* experiments were vitiated by *the fact that* no *consideration* had been given to the *possibility that the* children suffered from hypothyroidism, and that iodine was the limiting factor in their inability to grow On seeing these undergrown children it is astonishing that any clinician could have *overlooked* this, apart from the fact that Duisburg is, I believe, in a goitrous area The effects of the secretion of the thyroid on protein *fat*, carbohydrate, and calcium metabolism, on nerve muscle function, on reproductive activity, and on resistance to infection are well known [3]

The *following* data *from* these experiments support this contention

At the start of the studies 5 children at Duisburg and 3 at Vohwinkel had thyroid enlargement, at the end 64 at Duisburg (66%) and 27 at Vohwinkel (50%) had enlarged thyroids The protein range at Duisburg was 61–73 g, at Vohwinkel 51–53 g, and in both groups the weight increase in the same time was the same, so that it can be seen that the lower Vohwinkel supply of protein was adequate for growth, the excess protein at Duisburg merely going to supply energy and accounting for the increased hypothyroidism in that group This is the reason why the addition of milk was ineffective owing to the exhaustion of the available iodine and the *comment* "cannot be improved by a milk supplement" is *meaningless*

The delay in epiphyseal ossification is typical of hypothyroidism, quite a different radiological picture to that of rickets The continued presence of skin infection supports this contention, as *does* the complete absence of puberty in boy *of* 14 *Amongst* British boys puberty may start at 10 or 11 years *Iodine* was given, and this in itself should have suggested the nature of the deficiency The *puzzling* œdema is due to the unbalanced vitamin supplement added to the 70% extraction flour and causing a conditioned vitamin B_1 deficiency It is said that the children were so ravenous that they cleared every scrap of food and yet gave scraps of food to the monkeys in the zoo This does not appear to have been allowed for in the tables One wonders what else the children *did ?*

It can be seen therefore that there are no grounds for Professor McCance's conclusions, as the question of iodine being the limiting factor in failure of growth was not considered, and the internal evidence in the experiments strongly *suggests* that it was

"Man cannot live by bread alone" It has never been claimed *that* man can subsist on wholemeal bread alone but with other foods it enhances their combined nutritional value It is astonishing that the claim should be made that the experimental diets were nutritionally adequate, when the subjects of the studies are shown at the end to have enlarged thyroids, skin sepsis, delayed puberty, bad teeth, and delayed epiphyseal ossification —and at an age well below that in which they will be called upon to sustain all the vicissitudes of life

Restriction of Antibiotics ?

AMONG antibiotics erythromycin has the particular merit that it will often work when others have failed and from time to time we have urged our readers not to blunt this therapeutic weapon by using it for lesser purposes but to keep it sheathed unless nothing else will save the patient s life The advantages of doing this are plain, but so also are the difficulties, and the New Zealand government have decided that on this subject advice to doctors must now be reinforced by restrictions Because a number of children have died from infections by organisms no longer vulnerable to any antibiotic, they have decreed that, from Feb 1, New Zealand doctors shall be able to get erythromycin only through hospitals and only for the treatment of diseases which do not respond to other remedies This announcement by the minister of health, Mr J R HANAN, will arouse interest in many other countries, for, like the ban on heroin, the action now being taken may be regarded as an interference, by a government, with the doctor s freedom to treat his patients in whatever way he chooses

Looking at it bacteriologically and epidemiologically, there seems everything to be said in favour of the New Zealand decision When penicillin was first made available to civilian hospitals in 1944, in desperately small quantities its use as a life-saver was one of the spectacular advances of our time Those who had the hard task of allotting the scarce supplies will remember the many painful decisions they had to make, and the early days of penicillin were often darkened by the need to refuse but they were also lightened by the remarkable efficacy of the drug when it was used in the right way in the right cases In those days of scarcity a few skilled hands achieved excellent results and there were no mysterious and fatal forms of enteritis and no other complications due to sensitised patients and resistant organisms Now that antibiotics are plentiful, cannot the benefits of the lean years be restored, without their sufferings, by restricting the use of these substances, by common consent ? On purely scientific grounds it is hard to see why such restriction should not have the desired effect, if it is wisely and firmly applied, for, when an antibiotic is used less widely, the number of bacteria resistant to it diminishes swiftly If the New Zealand plan is to do what is intended, the hospitals, of course, will have to be even more sparing than the general practitioners in their own use of erythromycin for it is hospitals not sickrooms in the home, that are the great sources of antibiotic-resistant organisms We hope, therefore that Mr HANAN has told the hospitals to go very carefully in their own use of erythromycin Provided this vital point is covered, there are very good reasons for keeping one or more antibiotics in reserve for use in the last resort

But how exactly should the restriction be secured ? Some doctors are notably careful in their prescription of antibiotics, and it may be that the proportion who take thought about this has increased as more and more accounts have been published of the dangers of abusing these agents But it is still unfortunately true that the habit of giving antibiotics unwisely and even casually is the cause of much avoidable disability to patients and it would be over-optimistic to suppose that the mere publication of advice is enough to ensure that a drug such as erythromycin is used only when life is in imminent danger It would no doubt be easy to arrange for a suitably qualified group of doctors to meet from time to time to survey the antibiotics in use and to recommend that one or other should be ' rested ' long enough to restore its full power, but difficulty might well arise as soon as a move was made to give such recommendations the force of law It is possible that the kind of restriction now applied in New Zealand would be found acceptable here because its pattern resembles that already adopted for the distribution of important drugs while they are still scarce, and because it does not in fact embody anything like a complete ban On the other hand, recent happenings have made it seem likely that a regulation on the New Zealand pattern would be resented in this country Thus, paradoxically, it looks as though a course of action which most doctors would acknowledge to be sound scientifically, and necessary for the good of patients may be neither voluntarily adopted nor tolerated if imposed It is evident that, as a profession, we must try to discover means of bringing to bear upon the interests of all patients whether known to us by name or not the kind of wise judgment and resolute action which a good doctor prides himself on giving the patient directly in his charge The New Zealand decision should make us think again about the way in which antibiotics are being used in our own country, and we should also consider from whom, if not from a Government, doctors would accept direction on such subjects

Sulphonamides and Hypoglycæmia

DURING a clinical trial of the chemotherapeutic action of *p*-amino benzene-sulphonamido-isopropyl-thiodiazole, JANBON and his associates[1] noted that this substance produces a fall in the blood-sugar level which may be so profound as to lead to hypoglycæmic coma This clinical observation was confirmed by experimental studies in rabbits and dogs[2] Oral or subcutaneous administration to dogs results in hypoglycæmia, the blood-sugar falling to as low as 40 mg. per 100 ml within five hours With continued administration, chronic hypoglycæmia develops and may cause irreversible neurological changes similar to those observed after prolonged insulin hypoglycæmia The decrease in blood-sugar is proportional to the concentration of this sulphonamide in the blood, and experimentally, hypoglycæmia is obtained with much lower doses if the sulphonamide is injected directly into an artery supplying the neck of the pancreas After total removal of the pancreas there is no hypoglycæmic action, but it persists if as little as a fifth of the gland is left A study of several thiodiazole area of the mamma, (2) the female sex hormones might take on local antigenic properties by passing through a similar denaturing process due to the radiation injury, or (3) in the mammary region, denatured cholesterol derivatives (the breakdown products of healing tissue cells, rich in cholesterol, and exposed to the heavy injury of irradiation with 6000r) might act as antigens and produce multivalent antibodies directed against a series of structurally related steroid hormones

---

[2] Loubatières A. *C.R Soc Biol Paris* 1944, 138 766

Whatever the explanation, it seems that the primarily fixed antibodies, or those becoming sessile under the influence of the X-irradiation, manifested themselves by a pronounced allergic reaction Since general sensitivity to testosterone propionate (though in lesser degree) was demonstrated, and the Arthus like local necrosis suggested either an immediate or a delayed hypersensitivity,[2] antigenicity of the endogenous steroid hormones seems the most probable explanation

OPPORTUNITIES IN AUSTRALIA

SIR,—I read with interest your correspondent's article last week I had a practice for several years in a small country town, such as is mentioned by your correspondent I should go further and say that to earn this figure of £A8000 per annum was exceptional and that £A5000, with one-third expenses, was much more general I do agree that most Australians welcome English graduates They also have a very high standard of all-round general practice, particularly surgery

I should finally like to add that it is a well-worthwhile adventure for anyone without family restrictions and that, as stated, three years would see him well established

Manchester R I JOHNS

INTERMITTENT CLAUDICATION AND SYMPATHECTOMY

SIR,—I have read with great interest the paper by Mr Mavor (Oct 15) in which he states that in the patients he has reviewed by questionnaire sympathectomy has had little or no alleviating effect on intermittent claudication due to atherosclerotic occlusion of large arteries Although he has cited the observations of previous workers who have maintained that benefit has been obtained in half or more of the patients treated, he has not mentioned any results similar to his own I should therefore like to draw attention to my own observations[3] which support Mr Mavor as to the ineffectiveness of sympathectomy in claudication It is of interest to consider the reasons for the differences between the reported observations

1 There is the patient's tendency to try to please the surgeon On looking over my records, I have observed that on the day when the surgeon noted that the patient was much better and could walk further, according to my notes his walking distance was unaltered I am rather surprised that Mr Mavor's results were not more "favourable" in view of his second question "Can you now walk further without leg pain ?" I tried to frame the question in a more neutral manner "Is the distance you can walk since operation more, the same, less ?"

2 After operation the patient can often walk further because he walks more slowly One patient was pleased because he could walk much further, but added "But of course I do not walk as fast" When asked what would happen if he walked at the same pace, he replied "Oh, then I could only walk the same distance as before, but I have now learned that it is better to walk slowly !"

3 As Mr Mavor has indicated, the relief of other ischæmic features may be taken into account by the patient when assessing the effect on the claudication In claudication, th muscle pain is often associated with paræsthesia of the f also occurring with exercise After sympathectomy, althou the former symptom may be unaffected, the latter may b alleviated

4 The symptom of claudication may be alleviated by placebo effect, even when assessed by a semi objective te such as noting the number of circuits a patient can walk a standard rate over standard steps[4]

These comments are not offered as criticism of M Mavor's findings, which are entirely in line with my own but merely to mention my supportive evidence and t put forward an explanation of the differences betwee the findings of Mr Mavor and myself on the one han and those of most previous observers on the other

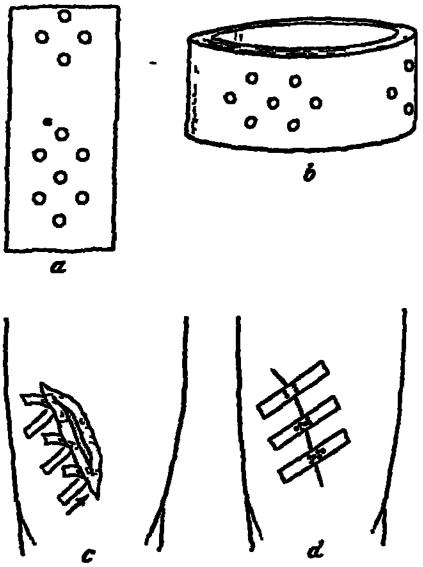
WOUND CLOSURE WITH PLASTIC TAPES

SIR,—For two years I have been investigating th closure of wounds with plastic tape The kind I now u is much like the 'Cellophane' tape that can be bough at any stationers, but it is made of polyester pla which stretches slightly in all directions and thus allow a little movement of the closed wound (figs *a* and *b*)

The tape is coated on one side with a special adhesi which is non toxic, and no skin reactions have been reporte from its use in over 1000 cases The adhesive is so compounde that it loosens on the sixth or seventh day after the tape applied, but the period of adherence can be varied b changing the proportion of certain ingredients The tape perforated at regular intervals by a pattern of small hole allowing drainage of wound secretions



To close a wound the edges are thoroughly dried an strips of tape are applied to the more mobile side of th wound (fig *c*) The tape will not stick when placed lightly on the skin surface, and consequently it can be moved to exactly the right place before pressure is applied to make it firmly adherent After the strips of tape have been attached to one side, they are used to pull the wound edges into exact apposition and then attached to the other side (fig *d*) An ordinary gauze dressing is then applied and left undisturbed for six days The tape will usually come away from the skin when the dressing is removed Rarely, healing may be so slow that another application of plastic tape is needed

One advantage of this method of wound closure is that it causes little pain, and it is therefore particularly useful in treating minor lacerations in children But in treating such lacerations additional advantages were observed

The average healing time was shortened by a day or more
The scar was less noticeable

[3] Barnett A J *Aust Ann Med* 1954, 3, 295

[4] Newman, H C, Barnett, A. J *Ibid*, 1955, 4 195

is established between virus and host—in other words, a latent infection Although the body remains infected there are no symptoms, and future reinfection with the virus, which would normally cause active disease, produces no effect. This state of affairs can be studied readily in the bacterial viruses. when a bacterial culture is attacked by a specifically active virus, some of the bacterial cells are lysed but others survive and are symbiotically infected with the virus the daughter cells inheriting the infection when the parent cells divide These symbiotically infected bacteria or lysogenic strains are immune to further attack by the same kind of virus although they remain susceptible to other viruses Some animal viruses have a less specific effect by which infection with one kind of virus protects against attack by another kind This protection may be due to saturation of vulnerable sites in the body by the first virus so that there is no suitable accommodation for the second intruder Another suggestion is that sometimes the second virus may be excluded by starvation, because the first has monopolised all the available metabolic activities of the host

It is becoming clear that immunity not attributable to classical antibodies can also arise in bacterial diseases Some protection against toxins can be conferred on animals by giving them large doses of toxoid It may be that specific receptors in the animal body are occupied by the innocuous toxoid so that the toxin is unable to get at these particular sites and hence cannot produce toxic effects Unlike the more usual immunity due to antibodies this protection develops immediately and disappears quite rapidly. In tetanus it has been shown that the attachment of toxin to brain tissue *in vitro* may be blocked by previous exposure to toxoid Further experiments throwing light on the mechanism of this process have been reported recently by DAVIES and WRIGHT[1] They concluded that the administration of toxoid did not permanently block the effects of toxin, but that there was active competition between toxin and toxoid for hypothetical receptor sites in the body On the other hand once the toxin had been fixed to brain tissue the toxoid could exert no protective action Animals which had been only partially protected from the effects of toxin by the administration of toxoid did not show the usual signs of tetanus, but paralysis developed as in botulinum intoxication. The cause might be the unmasking of a further component of tetanus toxin possibly peripheral in its action. There have been doubts about the wisdom of attempting to immunise patients in the so-called negative phase when they have already been exposed to infection. The administration of toxoid or vaccine at this stage might divert the protective mechanisms of the body and neutralise any small amount of antibody present thus allowing the invader to do its damage untrammelled On the other hand, if the immunising agent can exert the blocking and interference phenomena revealed by recent work it may be able to protect even when its administration coincides with exposure to infection. Further experience is needed to judge between these views

The two kinds of protection conferred by vaccines are seen clearly in the case of whooping-cough[2] After a single intraperitoneal dose of pertussis vaccine in animals there is first a sudden but transient protection against pertussis This protection reaches its peak in about ten days and then disappears. EVANS and PERKINS[2] suggested that it might be the result of interference of the type encountered in virus infections and it is presumably due to saturation of sensitive sites by the dead organisms in the vaccine so that the live bacteria introduced in the infective inoculation are unable to become established and multiply The second phase of protection—that dependent on the production of antibodies—appears more slowly but lasts much longer Protective antibodies cannot be detected in the blood after a single injection of vaccine but a second injection gives rise to detectable antibody. These observations can be applied in testing the potency of pertussis vaccines Animals are given the vaccine and later challenged with a live virulent culture to find what protection they have It is necessary to measure the lasting protection conferred by antibody formation and not the temporary interference effect. hence, the challenge dose should be given when the transient interference effect has subsided and the more permanent antibody effect alone remains With pertussis vaccines therefore the challenge dose should be given 30 days after the administration of vaccine and not as recommended[3] at present after 14 days, since the protection measured at that stage is produced by the precocious interference

Annotations

THE GUILLEBAUD REPORT

CHARGED three years ago with inquiring into the financial aspects of the National Health Service,[4] the Guillebaud Committee has listened patiently to almost everybody who has views on how the service might be improved Its report on which so many hopes have been founded is being published this week after we go to press but Dr Abel-Smith's article on the cost of the National Health Service which appears on p 198, reviews some very interesting basic evidence collected for the committee under the auspices of the National Institute of Economic and Social Research, which is now produced in book form by Prof R M. Titmuss and himself.

ANTENATAL SEXING

IT seems that a reliable method has been discovered of sexing the unborn child In a letter on p 202 Dr James reports that he has found it easy to determine the presence or absence of the sex chromatin in cells of aspirated amniotic fluid, and with reasonable care amniotic fluid can be obtained at any time after the twelfth week.[5] A preliminary report from Israel by Serr et al[6] has recently recorded the same observation Since it has been shown that the technique of nuclear sexing can be applied to cells scraped from the surface of squamous mucosæ, oral[7,8] or vaginal,[9] it was certain that the amniotic fluid and its cells would soon be investigated from this point of view *A priori*, it might seem unlikely that satisfactory preparations would be obtained. for the skin even of the fœtus yields only non-nucleated squames and the lining cells of the amniotic

CHILDREN IN HOSPITAL

SIR,—I very much enjoyed the stimulating paper by Professor Illingworth and Dr Holt (Dec 17) I would say, however, that this matter of children in hospital has been over-dramatised

In my experience—and this must be surely universal too—it is the *only* child, especially of elderly parents, or the *youngest* child of a large *family*, *especially* if spread out chronologically, that is *most* likely to become fretful (It was an only child that was portrayed in *A Two year-old Goes to Hospital*—a film that in my view has exerted an influence disproportionate to its real value, dealing as it does with only one case) In such circumstances it is the mother or both parents who fret more than the child, and who, becoming over-anxious, transmit *anxiety to their offspring*

Compared with other features of many children's lives—such as being left with neighbours while the mother goes to work, the distractions of television and films, and lax discipline at home and (through no fault of the teacher) at school—a stay in hospital is likely *to do little harm to a child's mental health* There is a tendency for certain parents to fob off their own shortcomings on to those of us (doctors and nurses) who work in hospital under increasingly difficult conditions

I entirely agree that every parent has a right to see his child when *ill in hospital, and daily visiting is the* rule here But we should see that the right is not abused, and that a sense of proportion is preserved

Ilford Isolation Hospital I M LIBRACH

TUBERCULOSIS STATISTICS

SIR,—At the end of each year both the Ministry of Health and the Middlesex County Council ask every chest clinic to state the number of patients removed from the tuberculosis register during the past year, because of death I find that this figure is then widely quoted as the tuberculosis mortality rate This is, of course, most misleading and fallacious as an appreciable proportion of the patients have died from some intercurrent disease while having treatable or treated tuberculosis

In my area, which serves a *population of about 150,000* people, the number removed from the register because of death in 1954 was 22, 14 succumbed to the disease itself, but 8 died from a separate condition For 1955 the figure is 22, 15 died from pulmonary tuberculosis and 1 died from tuberculous enteritis, but in 6 the death was not related to the tuberculosis This means that in these two years about a third of the deaths were not attributable to tuberculosis This is an appreciable *proportion*, and is likely to get larger in future years, so the annual number *removed from the* register because of death will become an increasingly worthless figure

We are also told that the *notification rate is not* falling, and that its constant high level is a reflection on the methods used to eradicate this disease *This is, to my mind*, illogical reasoning and quite unjustified

In the past only a small proportion of the total number of infected patients in the community were *found*, and these were for the most part young adults with well established disease accompanied by obvious symptoms *Today, I believe*, because we have extended our search we find most of the infected patients in an area at any given time, and the cases *discovered* now include many people over the age of 60, and a number of young people with minimal symptomless, but active, *disease* The fact that tuberculosis is becoming effectively *controlled* is best demonstrated by the rapidly falling percentage of children and young adults who have a positive tuberculin skin test[1]

For the time being, therefore, I am glad that the notification-rate remains high, as it means that our case-finding methods are effective, and if it is even h next year it will be a matter for congratulation, bec as the number of cases gets less, so the finding of th will be all the more difficult

I would, therefore, suggest that the battle again tuberculosis is being won more rapidly and efficien than certain official statistics would lead us to believe

Ashford Hospital,
Middlesex P E BALDRY

PERSONALITY CHANGES AFTER FRONTAL LEUCOTOMY

SIR,—Because of the repercussions from discussion of my book[1] in various places, including the lay press a as more will have seen these than will have seen the book colleagues have suggested that I comment on the ma issue

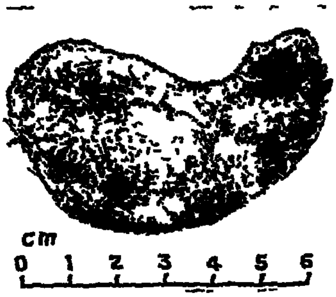
The book does not say that leucotomy is, universally, a bad operation, because it does not deal with this aspect It describes changes in the personality after severance of the frontal lobe by the standard operation, it describes not only the nature but also the extent of these changes Usually they are overshadowed in clinical practice by the modifications (if we may talk of them separately) in the various symptoms for which the operation is performed

Therapeutic procedures—e g, laparotomies—sometimes produce æsthetically undesirable results The consequence is accepted on pragmatic grounds So, after major leucotomy operations, there can be socially significant changes which are undesirable[1] Because of this, modified operations are in use I support the view that, as with *other treatments* in psychiatry, until we have something better they have to be, if appropriately employed, part of our available therapy

Oxford P MACDONALD TOW

TRICHOBEZOAR

SIR,—May I once again draw attention to this very interesting condition? When you published my account[2] of a case in which the hair ball had entered the small bowel of a child and caused obstruction, I thought that this was probably one of the first of its kind to be reported in Britain In 1928, however, Mr C Noon, of Norwich, had recorded[3] a case, in a woman aged 30, of intestinal obstruction due to four separate hair-balls I have very recently removed a hair ball from the small bowel of another child



The patient, a *girl, aged 7, had several* times been in hospital under the care of Mr J S Ramage with developmental anomalies of the renal tract, which included a supernumary kidney and a double urethra She had had *many* attacks of ascending urinary infection, and was *admitted* again on Dec 29 last with abdominal pain and vomiting This attack, however, was rather different, and she appeared to have a small bowel obstruction with a palpable mass in he type 3 strains which have been shown by Ryan nd others[11] to be the cause of pharyngo-conjunctival ever, and Jawetz s strain seems to be a new type hich has been called the Trim or type-8 virus Sero-ogical investigation of the type-8 virus[12] showed that 25 cases of epidemic kerato conjunctivitis occurring between 1951 and 1955 all showed a convalescent serum itre of 1 in 10 or greater, and only 2 of 29 sera from other eye conditions investigated by Jawetz showed such titres

---

[1] Grenville Mathers, R *Lancet*, 1955, ii 1341

[1] Personality Changes following Frontal Leucotomy London, 1955

[2] *Lancet* 1954 i, 761

[3] *Brit med J* 1928 i 342

It seems that there is a definite association between epidemic kerato conjunctivitis and these A P C viruses, their known resistance to antiseptics might well explain how transmission occurs by instruments used in ophthalmic practice There is, however, a certain amount of evidence that other agents may also produce the disease, for not only are the viruses isolated by the early workers very different from the A P C group, but there is also a difference in the clinical picture In the more widespread epidemics seen by Wright and by Sanders there were definite constitutional symptoms, which the later workers do not mention Thus, it is possible that the condition may have more than one cause, as is borne out by the occasional isolation of herpes simplex virus from these cases

PROGRESS IN NUCLEIC-ACID RESEARCH

THE self-duplicating plant viruses such as tobacco mosaic virus, are chiefly composed of ribonucleoprotein (6% ribonucleic acid [R N A] by weight), and they have therefore proved important tools for the study of protein synthesis This gives added interest to the report[13] from Stanley s laboratory of the successful splitting of the tobacco mosaic virus into R N A, and protein, and the subsequent recombination of the fragments to form active virus One sample of the virus was treated with dilute sodium carbonate to remove and degrade the nucleic acid, leaving the protein more or less intact, while another sample was treated for a short time with a dilute detergent which degraded the protein but left the R N A intact Both components were demonstrated to be free of intact virus If both fragments were brought together in aqueous solution at pH 6 in the proportion of 10 parts protein to 1 part R N A the solution began to take on the opalescent appearance of a solution of virus and could be shown to contain active virus in amounts which steadily increased reaching a maximum at twenty-four hours Typical particles of virus could be detected in the solution by electron microscopy although none appeared to be present in either of the separate components As earlier work[14] had shown that the virus particle consisted of a strand of R N A surrounded by a helix of protein, the separation of the components had to be achieved without altering the arrangement of the doubtless specific sites on each fragment which bind the two together by salt like links and by hydrogen bonds The first crystallisation of an animal-infecting virus (a strain of poliomyelitis virus) was announced at almost the same time from the same laboratory

Modern views of the function of the cellular nucleic acids, R N A and desoxyribonucleic acid (D N A) tend to associate D N A with the carriers of hereditary features and R N A with morphogenesis and with protein synthesis But a recent important paper by Mirsky and his associates[15] has shown that D N A may also be directly concerned in protein synthesis Isolated calf-thymus nuclei were able to incorporate C^{14}-labelled alanine into nuclear proteins, and this ability was progressively reduced to about 15% of the original level by successive destructions of the D N A by desoxyribonuclease Furthermore, the R N A contained in the nucleolus appeared to be less closely connected with this protein synthesis since 30% of the R N A present could be removed by ribonuclease treatment without affecting the power to synthesise protein from alanine The proteins synthesised under these conditions seemed to be those closely associated with both types of nucleic acid and not the simpler histones of low molecular weight

In general however there seems little doubt that protein synthesis is usually more closely connected with R N A than with D N A For example the only known function of the silk gland (which is very rich in R N A) in the silkworm is to synthesise the protein silk The same is true for all proliferating tissues and for those cells which secrete enzymes Embryonic tissue which is differentiating as well as growing, is also rich in R N A During intense physiological activity unconnected with active protein synthesis (in the heart and kidney, for example), there is no such correlation with R N A content of the organ

Another recent achievement also concerns R N A although it is possible that the results and techniques may be applicable to D N A in due course The R N A macromolecule may be considered as a large number of linked mononucleotides, each nucleotide consisting of a heterocyclic base, linked to a sugar, ribose which bears a phosphoric acid residue (base-ribose OPO_3H_2) Elimination of water between a sugar hydroxyl group and an –OH of a neighbouring phosphoric-acid residue builds up the macromolecule The hydrolysis of the macromolecule to single mononucleotides can be accomplished by alkalis or by enzymes (ribonucleases) but until recently the reversal of this reaction had not been accomplished Ochoa and his colleagues[16] have now found that if an enzyme isolated from *Azotobacter vinelandii* is allowed to act on a solution of a nucleoside diphosphate [base ribose O PO(OH) O PO(OH) OH] then a macromolecule is formed by elimination of inorganic phosphate In this way, Ochoa et al have built up from adenosine diphosphate a poly-adenine nucleotide which had many of the physical and chemical properties of a typical R N A Similarly starting from a mixture of the diphosphates of the naturally occurring ribonucleosides (base-ribose) they could build up an even closer model of a naturally occurring R N A The applications of this work to chemotherapy (by providing a source of "R N A" containing unnatural nucleosides in particular) are exciting At present, the corresponding diphosphates of the desoxyribonucleosides are not available, but when they are, it will be interesting to see whether the same enzyme, or possibly a hitherto unknown one, will be able to convert these diphosphates into a D N A -like macromolecule The four naturally occurring bases in R N A have recently all been detected as nucleoside diphosphates in the acid soluble fractions of animal tissues The early suggestions that this acid soluble fraction would provide precursors for nucleic-acid synthesis[17–19] were strengthened by some of the studies of isotope incorporation[20 21]; and they now seem to have been directly confirmed

PRINTING OF THE LANCET

A DISPUTE in the printing trade is causing difficulty in the production of this and other journals We hope to continue the distribution of our weekly issue at the usual time, but at present we are subject to certain restrictions There may also, we regret to say, be delay in the supply of reprints for scoring When the women had been delivered in Aberdeen Maternity Hospital, their labour was classified by one of the senior obstetrical staff using Stewart and Bernard's classification[3] At no time did the obstetrician or myself discuss the inventory scores or the labour classification As about 90% of all Aberdeen primigravidæ pass through the Antenatal Clinic and are delivered in hospital, any selective factor likely to cause misinterpretation of the results is virtually excluded.

[21] Goldwasser F *J Amer chem Soc.* 1955 77 6083

50 patients were excluded from the analysis, mainly because of "spoiled" replies or because (in 11 cases) they were delivered elsewhere Of the 850 women who completed the inventory, 259 (30%) had significantly high 'lie" scores, and this agrees with the proportion (32%) in my previous investigation The distribution of major uterine dysfunction between the two groups was as follows

—	High 'lie' score (259)	Low "lie" score (591)	Total (850)
No with major degrees of uterine dysfunction	7 (*2 7%*)	5 (*0 8%*)	12 (*1 4%*)

It will be seen that in labour 1 in 37 patients in the group with high "lie" scores had a major degree of uterine dysfunction, compared with only 1 in 116 patients with low scores

These results support the hypothesis of a "dysfunction temperament," but further research is indicated

I again thank Prof D Baird and Prof W M Millar for their valuable help I am also grateful to Mr W Z Billiewicz, of the Social Medicine Research Unit of the Midwifery Department, Aberdeen, for his statistical evaluation of the results I wish to thank the staffs of the Aberdeen Antenatal Clinic and the records department of the Maternity Hospital for applying the test

EFFECT OF COLCHICUM EXTRACT IN CHRONIC MYELOGENOUS LEUKÆMIA

Sir,—In the following case of chronic myelogenous leukæmia administration of a colchicum extract containing demecolcin caused a prompt and sharp fall in the white blood cell count and an unusual increase in the blood-urea level

A 21 year-old woman was admitted to hospital on Sept 29, 1955, with chronic myelogenous leukæmia On examination there was enlargement of the liver and spleen (28 cm beyond the costal margin) Blood examination revealed Hb 6 4 g per 100 ml, red cells 2,260,000 per c mm, hæmatocrit 20%, and white cells 362,000 per c mm

RESPONSE TO THERAPY WITH A COLCHICUM EXTRACT

Date	Days of therapy	White blood cells (per c mm)	Blood uric acid (mg per 100 ml)	Spleen enlt (cm)	Other manifestations
Sept 29		362 000		*28*	
Oct *5*	1				
,, 7	3	*297 000*			
,, 10	6				Diarrhœa
,, 11	Stopped	86 000		22	
,, 12					Rash
,, 13			51		
,, 14		12 400			Necrosis of lt tonsil
,, 18			5 7		
,, 19				*19 5*	

On Oct 5 treatment with a colchicum extract (containing demecolcin, a new alkaloid isolated by Santavy and Reichstein[4] from *Colchicum autumnale*) 5 mg daily was started, and this was continued for six days (total dose 30 mg) The fir are summarised in the accompanying table

Such a rapid leucolysis with a consequent increase in the blood-uric acid level to 51 mg per 100 ml does not seem to have been reported previously

PLAGIARISM?

Sir,—James Parkinson in his original essay on the Shaking Palsy, written in 1817, describes the onset of the illness as follows

"So slight and nearly imperceptible are the first marks of this malady, and so extremely slow is its progress, that it rarely happens, that the patient can form any recollection of the precise period of its commencement"

Over thirty years later Thomas Addison describes the beginning of the illness now known as pernicious anæmia

"It makes its approach in so slow and insidious a manner that the patient can hardly fix a date to his earliest feeling of that languor which is shortly to become so extreme"

The similarity is striking Can any of your readers confirm or refute that Addison was guilty of *plagiarism*?

HYPEREMESIS GRAVIDARUM

Sir,—The value of direct hypnotic suggestion in hyperemesis gravidarum is recognised[1-4] Little, however, has been said of the psychological mechanisms at fault The psycho analytic viewpoint stresses the symbolic ejection of the unwanted fœtus The following case illustrates a modern hazard in the formation of the symptom complex

A multipara, aged 30, was seen in a distressed and dehydrated state She was eight weeks pregnant She said that "a horrible feeling of sickness goes on all the time I cannot keep anything down" During her first pregnancy she had slight vomiting and nausea, which disappeared spontaneously at the thirteenth week Her childhood had been insecure Her father abandoned the family when she was three years old She was the youngest child and was always "spoilt"

She had been an inpatient in hospital for three weeks without improving In view of the gross dehydration and rapid loss of weight, hypnosis was immediately induced and direct suggestions were given to combat the sickness Two days later she reported that the sickness was less and that she had begun to eat a little for the first time in six weeks

No attempt at analysis was made except to say, at the second interview, that these cases represented a desire of the mother to get rid of the fœtus through fear, guilt, or other anxiety The patient denied that this was so in her case She was eating well by the fourth interview, but excessive salivation, both diurnal and nocturnal, proved troublesome At the fifth and last interview she explained that she had been frightened at the first pregnancy by learning that she was *rhesus negative* She was hypnotised and told that she would have no further fear and the salivation would stop On waking the patient said "I have had a sudden thought I was told that if I was rhesus negative I would be all right for the first baby but the second one might be deformed or born dead" This was the crux of the situation She was re hypnotised and told that she would have no further worry about the pregnancy of £6 million in the net cost of the pharmaceutical service resulted from a rise of £12 million in gross expenditure, offset by £6 million in revenue from charges. Increases in quantity, the substitution in prescriptions of proprietary for non proprietary articles, and the development of new products generally have all played important parts in causing the increase in cost. But as a whole we believe that the information collected about this service is sadly inadequate. It is not possible to record in useful quantitative terms what has happened.

The trends in cost of the dental and ophthalmic services have been similar. In total they declined in cost by £37 million. The charges introduced in 1951 and 1952 raised £10 million and reductions in the rates of payment of dentists saved £13 million. The remaining fall of £14 million was not entirely due to the indirect effects of changes. There is evidence that demand would have declined anyway after the abnormal arrears of needs had been at least partly dealt with.

A major part of the rise in expenditure by local authorities (£7 million of the £11 million increase from 1949–50 to 1953–54) was the result of rising prices. The rise of £4 million in the real volume of goods and services purchased occurred principally in the ambulance, domestic-help, and home nursing services.

Capital Expenditure

Capital expenditure by the National Health Service (on fixed assets) has been relatively small. About £12 million has been spent each year. As prices of building work and other capital assets have risen substantially over the period, the *real* rate of capital expenditure has progressively declined. The rôle of the health service in national capital formation has been small and declining (from 0.8% to 0.5%). Nearly all the capital expenditure has been devoted to the hospitals. About 10% of expenditure has been on new hospitals and major extension and a further 21% of expenditure has been on ward accommodation. Expenditure on accommodation for staff has accounted for 16% of the total.

The hospital surveys during the 1939–45 war drew attention to the inadequate state of hospital buildings. "Complete demolition" was recommended in a number of cases as some buildings were "unfit for any human habitation." A higher proportion of hospitals required substantial extensions and adaptations. The surveyors wrote of hospital buildings in the North-western area "considering the high place which England takes in the medical world, perhaps the most striking thing about them is how bad they are." It was generally agreed that the hospitals taken over in 1948 were too small, too numerous, and too old. In fact, approximately 45% of all hospitals were originally erected before 1891.

A high level of hospital building was expected to be achieved under the National Health Service. These hopes have not been fulfilled. The rate of fixed capital expenditure on hospitals has averaged about one third of the pre war rate in real terms. At this rate it would take over 200 years to replace our stock of hospitals.

The Hospital Population

The General Register Office generously undertook for us a special tabulation of the 1951 census schedules for all hospitals in England and Wales. This has drawn attention to the importance of demographic and other social factors which influence the demand on hospitals.

Compared with the demands made by single men and women (and, to a lesser extent, the widowed), the proportion of married men and women in hospital, even at the age of 65 and over, is extremely small. Among married men and women, the rise in the proportion in hospital with advancing age is not at all dramatic, it does not reach very high levels even after the age of 75. For all types of hospital, and in proportion to their numbers in the total adult population, the single, widowed, and divorced make about double the demand on hospital accommodation compared with married people. About two thirds of all the hospital beds in the country occupied by those aged over 65 are taken by the single, widowed, and divorced. The married state appears to be a powerful safeguard against admission to hospital, particularly to mental and "chronic" hospitals.

If this "photograph" of the hospital population taken on one night in 1951 is a representative picture of hospital provision, many interesting questions are raised by it. Is marriage a shield against high morbidity ? Is high morbidity a shield against marriage ? How far is the hospital service acting as a family substitute for those who are ill equipped with husbands, wives, and children ? The existence or otherwise of surviving close relatives seems the most important single social factor governing the amount and distribution by age and sex of demand for hospital care—particularly from older people. This being so, it would follow that the past social structure of the population determines in some measure current demands for hospital care. The low marriage rates of forty and fifty years ago represent one important factor. A second is the relatively high mortality rates in the past among married couples in the working classes, which, in addition to the losses caused by the 1914–18 war, led to a higher incidence of broken marriages. One long run effect of the 1914–18 war which has an obvious bearing on hospital demand today is the present "abnormally" high proportion of elderly widows. A third factor is the decline in family size and the survival into old age of more childless married men and women.

As regards the future, the substantially higher marriage-rate which has now prevailed for several decades and the considerable fall in the proportion of marriages broken by death are two encouraging features. The Government Actuary's estimates of the population of Great Britain in 1979 shows no significant change in the actual number of single people of pensionable age. The much publicised increase in the aged is expected to consist very roughly of two million married persons and of half a million widowed and divorced women, the groups which make much lower demands for inpatient care.

The Future

Changes in the marital state of the population would need to be included in any attempt to estimate the future cost of the National Health Service. Information on this aspect, however, was available only for the hospital service, but we were able to assemble some scattered information on the use made of the National Health Service by different age and sex groups of the population. From this, we calculate that a higher proportion of the cost of the National Health Service is devoted to the medical care of those under 15 (including confinements) than to the medical care of those aged 65 and over.

These estimates of the use of the service by different age and sex groups have been used to calculate approximately the additional future costs arising *solely* out of projected population change taken as an independent, isolated factor. Changes in age structure *by themselves* are calculated to increase the present current cost of the National Health Service by 3½% between 1951–52 and 1971–72. A further increase of 4½% is attributable to the projected rise in the total population of England and Wales (using the official projection figures). In total, therefore, population changes *by themselves* are not likely to do much to the future cost of the Service.

All these conclusions should reassure those who feared a continuous and steep increase in the cost of the National Health Service. The real increase in cost has been negligible in view of changes in the population, and the share of the community's resources used on the Service has been declining. The cost of the National Health Service is clearly, if not severely, under control.

His energy spilled outside his work, and in 1950 he was able to preside over the new Manchester Medical Society, which, largely through his efforts, had grown out of the amalgamation of five local medical societies

His leonine physical appearance did not belie his strength. As a student he had been a useful rugby forward, and as he grew older he became an intrepid mountaineer He was a past member of the Council of the Alpine Club and a past president of the Rucksack Club He was a moving spirit in the Mountain Rescue Committee and in 1939 he became chairman Believing that trained rescue parties should be allowed in an emergency to use small amounts of morphine, he drew public attention to this by inviting the Home Office to take legal action against him for supplying morphine for this purpose In court he pleaded guilty and was fined £5 Soon afterwards the Home Office agreed to this extension of the use of morphine

W R D writes

"Quite early it became clear that Wilson Hey was an unusual type and would probably go far This prophecy was fulfilled in his later life His enthusiasm for any work he undertook was impressive He had an unusual quality of brain which almost verged on genius he was certainly original and he never hesitated to express his views in face of the strongest opposition He was not an easy man to know Underneath his suave and charming manner lay a deep understanding of the human element and a great kindliness He would fight to the last ditch for any cause which he decided was right, as was shown in his fight for the supply of morphia to the Mountain Rescue Club He had been ailing for a considerable time, but his work so obsessed him that he refused all advice to retire His name will ring down the corridors of the Royal Infirmary and Christie Hospital for many years to come In the last half century Manchester has produced a number of outstanding surgeons, and amongst them the name of Wilson Harold Hey ranks very high"

Mr Hey leaves his widow, Dr Elsie Hey, with two sons and two daughters, one of whom is a doctor

ARTHUR FELIX

D Sc Vienna, hon D Sc Belf, F R S

Dr Felix, whose death on Jan 14 we announced last week, was pre-eminent in his own field of bacteriology For nearly 40 of his 68 years he had been an international figure

Born in Poland, he completed his studies in Vienna, and during the 1914–18 war he was employed as a bacteriologist in the Austrian army Working for part of the time in field laboratories, often under adverse conditions, he gained much experience of exanthematic typhus, and in conjunction with Weil he isolated the non-motile variant of proteus that reacted specifically with the sera of typhus patients (the Weil-Felix reaction) It was also with Weil that he observed the O and H types of salmonella colonies corresponding to the flagellated and non-flagellated state of the bacteria from this they worked out the two bacterial antigens, the heat-stable O (somatic), and the heat-labile H (flagellar) After the war they collaborated in Prague, and Felix always held Weil in grateful recollection

In 1921 he went to Palestine in accordance with his Zionist principles He remained there, as bacteriologist to the Hadassah Medical Organisation, until 1927, when he came to England and entered the Lister Institute There, happy in his friendship with Ledingham and in the congenial atmosphere he found, he settled down to one of his most profitable periods At first, with Dr Muriel Robertson, he demonstrated H and O forms of the anaerobes *Clostridium tetani* and *Cl septicum*, and from the O antigen of the latter they produced an antibacterial serum, devoid of antitoxic content, which was of theoretical interest, though it had no practical application to the treatment of gas-gangrene His most important work at the Lister Institute, however, was his concentrated investigation of the salmonellas and the discovery of the Vi antigen in the typhoid organism, and it was the characteristics and behaviour of salmonellas that continued to engross him after he joined the Emergency Public Health Laboratory Service in 1939 and became director of the Central Enteric Reference Laboratory and Bureau at Colindale when it was established just ten years ago

Looking back over his career one is struck by the ordered progression of his studies His research outlook was essentially practical, and his activities, applied to the control of infection, seemed to follow a definite plan. He began by investigating the nature of the organism responsible, and establishing exact methods of diagnosis, then he passed to prophylaxis, and finally to the development of biological tools for exact epidemiological inquiries

The Weil-Felix reaction was useful and important, but his contributions to fundamental bacteriology arose out of the very accurate investigations of the proteus X organisms and the non-motile variants, and led to the demonstration of the double antigen complex—somatic and flagellar—in motile bacteria More than ten years previously Smith and Reagh had observed that normal hog-cholera bacilli agglutinated differently from non motile variants, but the significance of the observation had not been fully appreciated In rediscovering the phenomenon Weil and Felix investigated it very thoroughly and showed that the large-flaking agglutination of motile organisms was associated solely with the flagella and that the fine granular agglutination seen with the proteus OX was seen only in non motile organisms

The extension of the proteus studies to the typhoid paratyphoid organisms was the next step, and on the greater part of this Felix worked alone His later observations on the O-inagglutinability of living cultures of some strains of typhoid led to the discovery of the third type of antigen (Vi), and then his endeavour to prepare an improved typhoid vaccine, with the new antigen unimpaired, resulted in the alcohol killed alcohol-preserved T A B vaccine

The persistence of Vi-antibody in a significantly high proportion of typhoid carriers further extended his epidemiological interest, and with the publication of Craigie and Yen's work on the Vi-bacteriophage types of the typhoid bacillus he was quick to seize the opportunity of using this discovery and developing it further for the fine classification of known typhoid carriers and as an epidemiological tool

As a scientific worker, his strongest characteristic was his capacity for studying a problem with persistent attention, and on one occasion he described himself as an instrument tuned to a single note But he never lost interest in any subject he had touched, and to the very end he had as great an interest in the Weil Felix reaction as in the determination of phage-type in an outbreak of paratyphoid fever

H J B writes

"Felix's work was characterised throughout by the simplicity and clarity of the design of his experiments He always used simple equipment and he relied on accurate observation, exact technique in performance, and the inclusion of all possible controls in every test His laboratory records were models of perfection, nearly all in his own neat hand writing on foolscap sheets, carefully filed and stored over the years He had complete confidence in the correctness of his observations and the reliability of his experiments and their records This made him a fearless adversary in any controversy on matters concerning his own work, and if the necessity arose he never hesitated, in this connection, to speak forcefully on what was in his mind

"He did not profess to teach, but he was an excellent instructor whether in person or by his written word My first experience of this came many years before I met him Just after the first world war, when I was working in Constantinople, many cases of typhus fever were being received from the Crimean area, and I found the precise and detailed instructions for the maintenance of the proteus OX strains and the performance of the Weil Felix reaction that originated from him of the greatest help The importance of using only the non motile variant of the proteus X strains for the for mass treatment often suggest that there were sporadic epidemics. Many parishes still had their pest-house—usually a cottage away from the centre of population—but few of these buildings have survived which can be identified with certainty.

A few weeks ago, I went to see Goosehill Camp at Binderton, a remarkable iron-age earthwork over 400 ft up on the eastern face of Bow Hill, which rises on the left-hand side of B 2141 from Chichester to South Harting. Goosehill is, no doubt, an archæologist's paradise, but I was much more interested in a delightful little house some 100 ft further up the hill—in fact, right on the top. This flint cottage has been adapted to suit modern requirements so far as its desolate position will allow but, by what can only be described as a miracle, two doors in it have survived which tell us a little medical history.

The doors are of deal boards polished with age. One shuts off the staircase from the sitting-room while the other does duty for the pantry. They are heavily carved with names and dates. The carving is not mere scratching with a pointed instrument: a really sharp tool in experienced hands made the record that in this cottage I. EVEN was INOCULATED 10th APRIL 1755 and RACHAEL CAPLIN was INOCULATED THE 5 NOV 1758. These two people were, like Jane Peacher (August, 1753), Miss Mary Day (1755), J. Newman (1758), A. Newman (March 19, 1758), Miss Mary Peachey, Mr. Peacher, Martha Adams, Jane Wyatt, and others, occupants of the pest-house. One gentleman who rejoiced in the unusual name of WHICHER SOUTER is said to have CAME TO BOW HILL 27 OCTOBER 1758 on the same day as Richard Caplin. G. Gas was there as late as 1781 and E. Souter in (?) 1788.

I examined the parish registers of West Dean, where entries for Binderton were made after the Commonwealth.

A Jane Peacher was baptised in March 1735-36, so that the person of that name at Bow Hill Cottage in 1753 would have been about 17 years old; she appears to have married James Piggot on Nov. 18, 1762, when Mary Peacher (perhaps her sister) was a witness to the ceremony. A Mary Peacher was married to John Eggar on Oct. 23, 1766, and Jacob Newman was a witness to a marriage performed in 1779. A visit to Stoughton, the parish immediately to the west of Binderton, provided evidence about Richard Caplin. Most of the headstones in the churchyard have been used to form a paved walk, but I found three to members of the Caplin family. A search in the parish registers showed a Richard Caplin as baptised on Aug. 3, 1746, died on Dec. 12, and buried on Dec. 14, 1758—facts which corroborated the epitaph on one of the headstones. Richard would have been 12 years and 2 months old if he was the patient who went to Bow Hill in 1758. On the other hand it may have been his father, also a Richard, who was buried at Stoughton on May 22, 1773.

These are the only links I could discover between parish records and the 19 names which I noted from the doors and their surrounds. One thing I did establish was that the names of none of the 19 people occur in the West Dean or Stoughton burial registers at or about the time of their sojourn at Bow Hill. We may assume, therefore, with some degree of certainty that the inoculations were successful.

It is unfortunate that no overseers' accounts for Binderton, West Dean, or Stoughton have survived to tell us the cost of administering this 18th-century isolation hospital in the heart of the Sussex countryside; but how many such hospitals have the names of former patients cut into their structure? The man who carves his mark for posterity is invariably dubbed a vandal, but for once we must approve the habit: it has given us a fragment of local history which might otherwise have been lost.

In England Now

A Running Commentary by Peripatetic Correspondents

Jimmy was seven years old and had leukæmia. Christmas was near when his mother and father learned the truth. The tragedy of medicine lay bare: neither compassion nor the faintest glimmer of a last hope could soften the cold truth. "We can do nothing. A few weeks perhaps, that's all: nothing more. Only a miracle could—"

With treatment Jimmy gradually improved. On Christmas Day he sat up in bed surrounded by toys and sweets, and his face shone with soap, joy, and cortisone. Soon his blood was normal and his marrow too; his spleen could no longer be felt, and his once enlarged glands had vanished. And his appetite knew no limits. "That's not the way to eat your dinner!" Sister was heard to cry. "Haven't you got a knife and fork?" Chips, ice-cream, strawberry jam, and 'Tizer' were his favourites, and on this diet he rapidly made up the weight he had lost. The day came when he was ready to go home. His pyjamas and slippers were put in a small suitcase, and with trousers, pullover, coat, and school cap, he walked slowly through the hospital gates between his mother and father.

That was two years ago. Since then Jimmy has had another Christmas and two birthdays, two Easters, and five school holidays. He was happy enough before his illness, but each month his parents tried to bring him even more happiness, knowing that it might be his last. Thrice more he walked out through the hospital gates. But the fourth time he was carried by his father, and last week he died.

Philosophers may argue that two years is a fleeting moment in the life of a little boy; that he might have found a greater peace in death two years ago than in two years hence; that a single sorrow borne once is lighter than many borne often. But the light in the eyes of Jimmy and his parents knew nothing of philosophy. We have no regrets.

* * *

I should like to be a nice examiner, but I don't know how. Candidates don't always give fluent and accurate answers in vivas, and they have to be helped along somehow. They don't like this; the bad ones are apt to be suspicious. Of course the examiner can change the subject, but even the dimmest candidate gets increasingly uncomfortable when the eighth topic is reached in seven minutes, and he goes out muttering, "They never gave me time to think about anything." The other extreme is also painful for all concerned. I have met candidates who were apparently willing to be silent *sine die*, but I have never had the nerve to keep quiet after putting one or two questions and see whether silence can be made to last for a whole fifteen minutes. So there is nothing for it but to ease things along on the middle path. Should I tell the candidate when he is wrong? How it demoralises the already nerve-wracked. Should I encourage his ideas? ("The damn swine led me right up the garden path.") I used to think that the only thing that really mattered was to be kind and friendly, and I hope that over the years I have schooled myself to consistent amiability. But now one of my students has come back from an oral examination by an examiner whose graciousness I have always admired. Evidently my student had been off form; some of his inadequacies had been revealed to him, and he was almost in tears about it. "You know, sir, they were so nice about it. That's what I couldn't bear."

* * *

Practice still is rural in the remoter parts of Lincs. True I go round in a car instead of a trap, and I am called by telephone rather than the midnight knock on the postern. But as I go I look for the red flag put out by the hedgeside. It is a signal. A patient at some remote farm has sent down to a road-side neighbour asking us to call. I go along twisting lanes, fortunate if there are no gates to be opened and shut. In the boot of the car are my stock mixtures and tablets, my syringes already boiled and ready for use, dressings, and apparatus for hæmoglobinometry and minor surgery.

from all over the world, and Oertel joined them The time spent in this stimulating and exciting atmosphere coloured his outlook for the rest of his life Wundt made him see the events of history and the phenomena of life from an objective scientific point of view During this stay he also studied comparative anatomy and evolution and the works of Goethe, Lessing, and Gillert

In 1897 he returned to America and in the next ten years he held university posts before in 1907 he was appointed director of the Russell Sage Institute of Pathology, New York In 1913 he came over to Guy's Hospital and worked on experimental nephritis and the development of the kidney In the following year McGill University invited him to become associate professor of pathology there and pathologist to the Royal Victoria Hospital In due course he was appointed to the chair of pathology

W G B writes

"Oertel's contribution to pathology was his insistence that it should be studied from a philosophical point of view and its backbone be composed of a strictly causal comprehension of pathological processes based on logical objective reasoning only This is clearly seen in the preface and introduction of the two books he wrote, *Pathology* (1927) and *Special Pathological Anatomy* (1939) His other contribution was his insistence that organs should be studied whole and that the study of the separate tissues of which an organ was composed did not represent the functional potentiality of the whole organ He made an extensive study of tumours to show that they had the ability to excite the tissues in their neighbourhood to produce stroma, blood supply, and a new nerve supply The steady flow of good papers which came from his institute was based on sound work, much of which was initiated or actually done by Oertel himself

"Oertel was a friendly, urbane, companionable man much absorbed by pathology and philosophy, he had a great admiration for Goethe He enjoyed good living and the company of friends He was a bachelor and since he retired in 1938 he had lived most of the time in London at the Devonshire Club"

JAMES DOUGLAS MONTGOMERY KERR

M D Edin, D P H, D C H

Dr J D M Kerr, a senior medical officer in the Edinburgh public-health department, died on Jan 9, at the age of 32 Born and brought up in Edinburgh, he was educated at George Heriot's School and the University, where he graduated M B in 1946 After serving as house-surgeon at the Royal Infirmary and house-physician at the Royal Hospital for Sick Children in Edinburgh he joined the Royal Air Force On his demobilisation in 1949, he returned to Edinburgh as a clinical assistant at the Sick Children's Hospital, and at the end of this appointment he joined the Edinburgh public-health department as an assistant medical officer in the child-welfare section He took the D C H in 1950

His energy and enthusiasm for work among children led to his being chosen to study retrolental fibroplasia among infants born in the city He submitted the results of his investigations as a thesis for the M D degree, which he obtained in 1953, and he published, with colleagues, several papers on the subject By this time he had decided that his main interest lay in preventive medicine, and in 1954 he took the D P H To enlarge his experience he worked for a time among the aged Two months ago he was appointed a senior medical officer in the Edinburgh public-health department

Two colleagues write "Douglas Kerr always set himself high standards and he showed considerable keenness both in work and in sport Already his researches had shown that he had an incisive and original mind In sport his special interests were rugby, at which he had represented Edinburgh against Glasgow in the inter-city as well as playing for Heriot's F P and London Scottish, and tennis at which he also excelled His cheerful manner and ever-present sense of humour earned him many friends not only among his associates in private and professional life but also among his patients Love of children was a constant feature of his pædiatric and early public-health work and his enthusiasm and sympathetic understanding also won him the confidence and gratitude of the old folk"

Dr H S PEMBERTON

J G F writes

"To some extent Pemberton was a difficult man to know, for he hated anyone to guess that he was a mass of kindness and emotion He did not give his friendship easily, but having done so nobody could be more helpful or more kindly He never forgot the slightest kindness done to him, and would return it a hundredfold, more if possible To him all patients were the same His job was to get them better and this he tried to do with all the skill, all the attention, and all the care he could lavish on them, and not without considerable success He will be remembered with gratitude by many people in Liverpool and district, but particularly by the diabetics At the time of his retirement there were over 1000 patients at his diabetic clinic, all of whom he knew by name and to each he gave individual attention To the hundreds of doctors who in their student days were on Pem's firm he taught that medicine began with the patient, and that the patient as well as the disease must be treated His ward rounds and outpatients were memorable, and no student ever left him without having learnt a great deal about the art of medicine"

Mr E R FLINT

A P B writes

"In the 1914–18 war 'Father Flint' ran the Leeds General Infirmary's surgical beds together with 200 military beds in old Outpatients This was made possible by his cast iron constitution and his indomitable energy His work in the operating theatre was astounding I can remember, as a student, giving 22 general anæsthetics for him for cases of the order of hernia during the afternoon and evening He was fascinating to watch and he had rather a stumpy hand which apparently moved slowly but with such precision that the work was done speedily He had only a student anæsthetist and two nurses to assist him, but the atmosphere of the theatre was serene and no tempers were lost While still R S O he probably opened more abdomens than any other British surgeon in his lifetime"

Sediment of amniotic fluid (Papanicolaou stain × 1100)

taken at birth contains many cells With a female fœtus most of these are basophilic with the Papanicolaou staining technique and have large vesicular nuclei Rosa and Fanard[4 5] demonstrated that they are desquamated cells of the fœtal vaginal epithelium Moreover, with fœtuses of either sex other cells are found, probably from the digestive and a few from the urinary tract The material desquamated from the skin consists only of platelets with pyknotic remainders or no nuclei at all

In the large basophilic cells in the amniotic fluid, where the fœtus is female, sex chromatin can easily be demonstrated (see accompanying figure) We found this in more than half of the nuclei suitable for study of morphological detail The Papanicolaou and Giemsa stains both give good results In the case of a male fœtus, most of the nuclei of cells found in the sediment are pyknotic, but some small basophilic cells have vesicular nuclei No sex chromatin could be found in any of these nuclei

It is thus possible to diagnose the sex of the fœtus from the sediment of the amniotic fluid by demonstrating the typical nuclear pattern Where amniotic fluid is tapped for therapeutic reasons the fluid could be tested in this way

Where the sex of a neonate cannot be established immediately after birth, sexing of nuclei could play an important rôle, by its simplicity and speed cytology is here the method of choice, and Moore and Barr's procedure with smears of the oral mucosa should be preferred in these cases

Histological Laboratory,
University of Amsterdam F JAMES

RETIREMENT BENEFITS FOR THE SELF-EMPLOYED

SIR,—Although most members of the medical profession are now accumulating retirement benefits under the National Health Service scheme, there will still be many who cannot make provision so far as earnings from their private practices are concerned, and I am sure that your readers will be as anxious as are other professional people that the proposals of the second Millard Tucker Committee should be implemented in the forthcoming budget

We all realise that since the war the level of taxation has been so high that very few people are now able to provide for their retirement by setting aside savings out of net income Employed persons are increasingly able to use pension schemes of one kind or another which enable provision for old age to be made year by year out of gross earnings

Self-employed persons are not able to enjoy the benefits of such schemes and are thereby placed at a disadvantage compared with those who are employed in industrial or commercial firms which have adopted statutory superannuation schemes The disadvantage is a very real one which is bound, sooner or later, to have an adverse effect on the independent professions

The subject has been most carefully reviewed during the past ten years and it is now two years since the Millard Tucker Committee reported Its conclusion was that the benefits which are available to ordinary employees should apply equally to persons who are self employed

These views were shared by the Royal Commission on the Taxation of Profits and Income, and it can be confidently claimed that there is no responsible body of opinion which would continue to deny to the professional self employed the benefits of pension schemes

So far as the professional men are concerned the cost would certainly be modest, and in any case would to some extent only represent a deferment, since tax would be payable when the pensions are paid Since the relief that is given is conditional upon regular saving, the economic effect would not be inflationary

I hope, therefore, that members of the medical profession will join with their colleagues in other professions in supporting the claim that the Tucker Committee's proposals should speedily find their way on to the Statute Book

Shortlands, Kent E KENNETH WRIGHT

MENTAL NURSING

SIR,—Recent issues of *The Lancet* have been characterised by an unusual and perhaps laudable emphasis on social and occupational aspects of psychiatry in mental hospitals Criticism, much of it ill informed, has been directed against such institutions by various individuals who have assumed the authority or right to castigate hospital authorities for a variety of reasons Hitherto we have dismissed these pontifications with the contempt they deserve The danger, however, is that the popular press will seize extracts from these pseudo authoritative pronouncements to entertain their less erudite readers

Now we are informed by Dr Hunter (Jan 14) that over the past twenty years the advances in psychiatric treatment largely comprise cunningly devised methods of restraint put forward under the guise of therapy Further, the corollary to the proposition, as stated, declares that mental nursing has degenerated to the level of virtually unskilled guardianship, hence the failure of recruitment to the service

It is difficult to believe that any experienced physician will accept such nonsensical pronouncements Dr Hunter's philosophy would suggest that all research in mental disorder should be abandoned and that his skilled team of nurses would thereupon take over This approach, together with perhaps a short course of psycho-analysis, would at once relegate all physical treatments and all sedation to the limbo By extension, he would then similarly treat all cases of traumatic delirium and confusional states associated with bacterial infection or toxæmia, still encountered in general hospitals

May we point out that the most perfunctory inquiry will reveal to Dr Hunter that practically every general hospital, except teaching units, is bedevilled by a similar acute shortage of nursing staff Dr Hunter may or may not have realised that these are times of full employment, that the reserve of both man and woman power is exceedingly small, and that for women greater emancipation and changing economic pressures have thrown open a whole host of vocational possibilities not extant twenty years ago In this regard the size of the nursing staff is by no means correlated with the amount of physical treatment Many hospitals in remote areas with comparatively little in the way of newer therapies experience as much difficulty in recruitment as do the others

We should like to inform him likewise that at the outbreak of war fifteen years ago Springfield Hospital had

"OEDÈME BLEU"

SIR —Dr Ida Macalpine and Sir James Paterson Ross (Jan 14) deem it ' impossible to discuss *œdeme bleu des hysteriques* without glancing at the history of the term ' hysterical ' They achieve this glimpse and in addition aver that the " term has impeded the understanding of mental disorders from earliest times " without mentioning the name of Charcot's great collaborator Pierre Janet

The latter's book on *The Major Symptoms of Hysteria* (1907) is a psychiatric classic Its perusal leaves no room for doubt that the word as used by Janet has secured a permanent place in the history of systematic psychotherapy It has, since his day, been consistently traduced by physicians and surgeons His description of the malady, however, remains of paramount clinical significance

London, W 1 MURDO MACKENZIE

RECRUITMENT FOR THE OVERSEA MEDICAL SERVICE

SIR —From personal experience I would like to support the views put forward by Mr Roaf (Jan. 14) I agree entirely that as a medical ambassador only the best is good enough ' It has to be remembered that many doctors in overseas territories have been trained in this country and know perfectly well who is who To presume that the registrar is able to advise them on the organisation of their medical services is quite absurd Consultants of recognised standing should be able to achieve much more in much shorter time, and a continual exchange of views with experienced specialists from this country would be of far greater value than long-term junior appointments A scheme of short-term secondment of consultants is also likely, apart from the purely technical point of view, to create confidence and good will

Harefield Hospital,
Middlesex. E NASSAU.

ARTIFICIAL HIBERNATION IN HEART-DISEASE

SIR.—In view of the discussions about the use of chlorpromazine that have appeared in your columns we thought it might be of interest to report some effects of artificial hibernation in a new field Our technique, applied in a considerable number of patients, has been essentially Laborit's method—i e , vegetative inhibition by a mixture of chlorpromazine, promethazine, and pethidine in a ratio of 1 : 1 2, supplemented in case of need by hypothermia

Two children with acute rheumatic pancarditis were desperately ill, and their cardiac function had not been improved by repeated digitalisation. Œdema had been uninfluenced by diuretics, and dyspnœa could not be relieved by any means The question then arose whether their chances could be improved by artificial hibernation One hour after treatment began, there was a dramatic improvement in their general state, and dyspnœa was entirely relieved On lowering body-temperature to 31°C and 33°C respectively, the pulse-rate and respiration rate fell to normal Within the next twenty-four hours diuresis was so copious (6 and 8 litres respectively) that œdema practically disappeared The lives of these children could not be prolonged for more than a few days Nevertheless this experience suggests that even in the gravest forms of acute pancarditis artificial hibernation may enable sufficient time to be gained for the condition to be controlled by other means

The diuretic action of hibernation was immediately tested in a number of other patients In two children with chronic rheumatic heart-disease, adequate diuresis could not be induced even by adult doses of mercurial diuretics and theophylline Two doses of the ' lytic cocktail " were given within half an hour, each of them containing 0·25 mg of chlorpromazine per kg body-weight, a mercurial diuretic was given at the same time The resulting diuresis was about three times as great as any previously attained. Both in these and in similar patients there was a rapid decrease in the size of the liver and in the extent of œdema In the same patients a similar diuretic effect was not elicited when, instead of the complete cocktail, one of its constituents was given with the diuretic

P V VEGHELYI

ALLERGY TO MALE SEX HORMONE

SIR —I have observed a curious allergic phenomenon in a 51-year-old woman during treatment of breast-cancer metastases with male sex hormone

The patient said that as a child she had had morbilli, scarlet fever and diphtheria Menstruation had started at the age of 12 years At the age of 30 she had been operated on for ruptured ectopic pregnancy The menopause began at 45 ; flushes had ceased In November, 1954 a firm nodular tumour was detected in the upper lateral quadrant of the left breast A radical mastectomy was performed followed by X-ray treatment with 6000r She gained 2 kg in weight In February, 1955, she felt tired, became dyspnœic, and had pain, associated with respiration, in the left side of the chest

On admission the secondarily healed mastectomy scar 10 cm. long, was surrounded by a sharply bordered area of pigmentation measuring 4 × 12 cm In the left chest were clinical and radiographic signs of pulmonary metastases and pleural exudate , and histological examination of the exudate revealed malignant cells Blood count . 3,600,000 red cells per c mm , hæmoglobin 72% (Sahli) · white cells 9600 per c.mm (differential count normal) Erythrocyte sedimentation rate 90 mm in 1st hour (Westergren) Urine . pus cells present

Hormonal treatment was started on March 29 with daily injections of 50 mg (2 ml) ' Oreton (testosterone propionate) Four days later the patient complained of itching of the scar The pigmented area became reddish swollen, and tender Administration of ' Antistin ' 0 1 g (2 ml) caused the itching to cease temporarily but continuation of this treatment produced discoloration and renewed itching A scratch test on the forearm revealed faint sensitivity to 0 1 ml oreton and also (a few days later) to 0 1 ml ' Androfort ' (another testosterone propionate preparation) On the same day we injected 0 1 ml androfort into the skin of the pigmented area near the scar , after three days an area of necrosis measuring 0 3 × 0 2 cm developed Control injections with sesame oil and saline solution gave no reaction at all. After four simultaneous injections of oreton and antistin the urticarial reddening subsided and the injections of the hormone were resumed without further reactions The patient went steadily downhill, and she left the hospital on June 13 in an extremely grave condition. She died a few days later at home Permission for necropsy was not granted

It seems indisputable that the reddening and itching of the X-ray-pigmented area was an urticaria-like allergic reaction, and this was proved by the immediate response to anti-histamine substance and the successful desensitisation Obviously the patient developed hypersensitivity to male sex hormone, though she had never before been treated with this The sensitivity was not to a particular preparation of the drug, because the scratch test was positive both to oreton and androfort

The fact that intracutaneous injection of 0 1 ml androfort produced an Arthus-like necrosis in the X-ray-pigmented area favours the assumption that local (sessile) antibodies were present

How did this sensitivity develop ? The short interval between the start of treatment with male hormone and the development of the urticarial reaction is against the possibility of sensitisation to the injected hormone It is, however, well known[1] that physical factors, such as X rays, may cause concentration of the circulating antibodies in the corresponding part of the skin ; and the antibodies thus become localised There are several possible sources of these circulating antibodies (1) the provoking antigens might be breakdown products of the endogenous androgens, this biochemical process having been influenced by the X rays in the highly vascular almost impossible, with the exception of pride of craftsmanship It would, in fact, be easier to attempt to forecast future trends, for the drift away from mining and cotton textile work, in favour of the newer engineering and chemical industries, seems likely to continue, and the further developments in these industries will require a different type of worker from the past, for even a push button operator must know which button to push and why

---

[1] Rajka E. *J Allergy* 1942 13 327

The manual worker of my boyhood, with his clay pipe his choker, and his dinner in a red handkerchief, is already a museum piece, and in his place has come a race of people who are already technically proficient, and who, in a short space of time, *must become more so* Such people will lead very different lives from their forebears In this connection it is instructive to note the comprehensive definition of automation presented at the First International Automation Exhibition held in New York in 1954[4] It was there defined as "the substitution of mechanical, hydraulic, pneumatic, electrical, and electronic devices for human organs of observation, decision and effort, so as to increase productivity, control quality, and reduce costs" A more simple definition has been given as "*the operation of machines by other machines*"

Community Living

The first essential is, of course, to be and remain alive and a very considerable portion of the revenue of the country *is devoted to* ensuring that most of us are enabled to do so For the purposes of the present paper, however, we can take these services—health, hygiene, pure and adequate food, and so on—for granted, and concentrate rather on how to "warm both hands before the fire of Life," to quote Walter Savage Landor These measures to preserve life and health are, however, effective only in so far as the people will make them so, and that is a matter of education It is not the prime *function of national health and welfare services to provide* excuses for absence from uncongenial work, or to cure diseases which should not have occurred Similarly the purpose of education is, presumably, to open a wider door than mere ability to read a table of football results, or instructions for the filling in of forms

Excluding his physical needs what *does* a man want? *Here it is tempting to bring out all the well-worn phrases* about a balanced emotional, intellectual, and spiritual *development*, but each man differs and generalities will not suffice First and foremost, however, he needs a sense of purpose, a place, a niche, in his community He needs, if he is a normal person, to feel a sense of personal responsibility for his daily life, and he also needs some outlet for the creative urge which is within everyone, and which if unsatisfied, may appear in the most *bizarre fashions*

It is customary to speak of the home as the place where self discipline, integrity, and a sense of responsibility are learnt, and to point to the association between broken homes and delinquency, but I sometimes wonder whether our educational system is at fault It must be tantalising enough for a child to begin to learn of interesting things, and then have *to concentrate* at an early age on a few special subjects for examination purposes *It must* be even worse for a boy to find himself in the "duds" class, or in a school for backward pupils, especially if he knows that he is only deficient in certain things, while he may be expert in others

Also, how much does our educational system take into account the future *life of the child? Does anyone ever* explain to him the various ways in which he might make his living, and the disadvantages of "dead ends"? Our great industries have many international ramifications Are children taught to associate the factories and workshops in their own town with the geography of their books? It would be a valuable experiment for the management to organise talks to, and visits from schools, and let the men do the talking At least the experiment could do no harm The children would learn something, and the men would benefit by the experience

It is at the next stage, the school leaving age, that the most searching questions need to be asked about the *present system We are, and rightly, proud of our youth* service in Britain It is, in the words of the official handbook, designed to provide for the leisure time activities of young people and to offer them opportunities "complementary to those of home, formal education and work" for observing and developing the personal resources of body and spirit and so help *them to become responsible members of society* But does anyone ever explain to these young people, without practical demonstration on a "*mock up*," how *to make* the best use of a home? Admittedly I have in mind the type of full sized model used by the Building Research Station in their experimental investigations into the comfort and working conditions of the housewife, and such realistic conditions would be too costly to be widely copied But one would imagine that housing authorities, *for* example, might find it profitable, in the long run, to lend an empty council house for this purpose which could then be furnished simply, and water, gas, and electricity boards could supply examples of their wares and demonstrate their proper use Boys would, I believe, enjoy seeing how electrical and other gadgets work, and girls would enjoy being shown how lighting, colour, and the proper *placing of furniture* or fittings, improve working conditions in the home Indeed it is not too far*fetched to suggest that* members of a senior class should "*run*" such a house *for* a week, including the cooking of meals, and thereby gain valuable information on family budgets If the house were open *for* parents to see if they wished, then adults would benefit also Such an experiment might do more good than many lectures on civic and community development

Does anyone gather these youngsters in groups and take them round the various industries in the area? When they have acquired a job, is it anybody's responsi*bility to take them through* the process *from* start to finish, so that they may see the machine of which they form part? In a small office the office boy soon becomes extremely knowledgeable, but a van boy sitting on the tailboard of a truck may know only *the name* printed on the side of it Small wonder if he jumps *off and* goes somewhere else

Quite seriously I would suggest that the federations of employers, the trade unions, and the Government *departments and nationalised* industries concerned, might organise, on an area basis, courses of instruction, with practical demonstrations, *for those* about to enter industry, together with an advisory service for parents For that matter it should not be beyond the wit of man to reorganise part of the National Service machine so that it would function as a preliminary training school for civil as well as military purposes, but without the element of conscription

The Future

It seems to me, as a mere onlooker, that we are stuck *about* halfway along *a* course *for* which the ancient learning has no precedents, for we now have this curious mixture of State control and private enterprise, with the former gaining in importance *It so happens that* I have spent some twenty one years in local and central government service, and, while I have the greatest respect for the civil and local government servants, *there is no doubt in my mind* that the State machine is not an ideal one when considering *industrialisation* and community living Rules drawn up on a national basis must be free from loop holes through *which the* rascal or the stupid may slip, grades must be standardised and rates of *pay adjusted to* those grades, Ministers must be protected and mistakes avoided With such a machine there is little room for experiment, for failures

"OEDÈME BLEU"

Sir,—Dr. Ida Macalpine and Sir James Paterson Ross (Jan. 14) deem it "impossible to discuss *œdème bleu des hystériques* without glancing at the history of the term 'hysterical.'" They achieve this glimpse and, in addition, aver that the "term has impeded the understanding of mental disorders from earliest times" without mentioning the name of Charcot's great collaborator, Pierre Janet.

The latter's book on *The Major Symptoms of Hysteria* (1907) is a psychiatric classic. Its perusal leaves no room for doubt that the word, as used by Janet, has secured a permanent place in the history of systematic psychotherapy. It has, since his day, been consistently traduced by physicians and surgeons. His description of the malady, however, remains of paramount clinical significance.

London, W.1. MURDO MACKENZIE.

RECRUITMENT FOR THE OVERSEA MEDICAL SERVICE

Sir,—From personal experience I would like to support the views put forward by Mr. Roaf (Jan. 14). I agree entirely that "as a medical ambassador only the best is good enough." It has to be remembered that many doctors in overseas territories have been trained in this country and know perfectly well who is who. To presume that the registrar is able to advise them on the organisation of their medical services is quite absurd. Consultants of recognised standing should be able to achieve much more in much shorter time, and a continual exchange of views with experienced specialists from this country would be of far greater value than long-term junior appointments. A scheme of short-term secondment of consultants is also likely, apart from the purely technical point of view, to create confidence and good will.

Harefield Hospital,
Middlesex. E. NASSAU.

ARTIFICIAL HIBERNATION IN HEART-DISEASE

Sir,—In view of the discussions about the use of chlorpromazine that have appeared in your columns, we thought it might be of interest to report some effects of artificial hibernation in a new field. Our technique, applied in a considerable number of patients, has been essentially Laborit's method—i.e., vegetative inhibition by a mixture of chlorpromazine, promethazine, and pethidine in a ratio of 1 : 1 : 2, supplemented in case of need by hypothermia.

Two children with acute rheumatic pancarditis were desperately ill, and their cardiac function had not been improved by repeated digitalisation. Œdema had been uninfluenced by diuretics, and dyspnœa could not be relieved by any means. The question then arose whether their chances could be improved by artificial hibernation. One hour after treatment began, there was a dramatic improvement in their general state, and dyspnœa was entirely relieved. On lowering body-temperature to 31°C and 33°C respectively, the pulse-rate and respiration rate fell to normal. Within the next twenty-four hours diuresis was so copious (6 and 8 litres respectively) that œdema practically disappeared. The lives of these children could not be prolonged for more than a few days. Nevertheless this experience suggests that even in the gravest forms of acute pancarditis artificial hibernation may enable sufficient time to be gained for the condition to be controlled by other means.

The diuretic action of hibernation was immediately tested in a number of other patients. In two children with chronic rheumatic heart-disease, adequate diuresis could not be induced even by adult doses of mercurial diuretics and theophylline. Two doses of the "lytic cocktail" were given within half an hour, each of them containing 0.25 mg. of chlorpromazine per kg. body-weight; a mercurial diuretic was given at the same time. The resulting diuresis was about three times as great as any previously attained. Both in these and in similar patients there was a rapid decrease in the size of the liver and in the extent of œdema. In the same patients a similar diuretic effect was not elicited when, instead of the complete cocktail, one of its constituents was given with the diuretic.

ALLERGY TO MALE SEX HORMONE

Sir,—I have observed a curious allergic phenomenon in a 51-year-old woman during treatment of breast cancer metastases with male sex hormone.

The patient said that as a child she had had morbilli, scarlet fever, and diphtheria. Menstruation had started at the age of 12 years. At the age of 30 she had been operated on for ruptured ectopic pregnancy. The menopause began at 45; flushes had ceased. In November, 1954, a firm nodular tumour was detected in the upper lateral quadrant of the left breast. A radical mastectomy was performed, followed by X-ray treatment with 6000r. She gained 2 kg. in weight. In February, 1955, she felt tired, became dyspnœic, and had pain, associated with respiration, in the left side of the chest.

On admission the secondarily healed mastectomy scar, 10 cm. long, was surrounded by a sharply bordered area of pigmentation, measuring 4 × 12 cm. In the left chest were clinical and radiographic signs of pulmonary metastases and pleural exudate; and histological examination of the exudate revealed malignant cells. Blood-count: 3,600,000 red cells per c.mm.; hæmoglobin 72% (Sahli); white cells 9600 per c.mm. (differential count normal). Erythrocyte-sedimentation rate 90 mm. in 1st hour (Westergren). Urine: pus cells present.

Hormonal treatment was started on March 29 with daily injections of 50 mg. (2 ml.) 'Oreton' (testosterone propionate). Four days later the patient complained of itching of the scar. The pigmented area became reddish, swollen, and tender. Administration of 'Antistin' 0.1 g. (2 ml.) caused the itching to cease temporarily, but continuation of this treatment produced discoloration and renewed itching. A scratch test on the forearm revealed faint sensitivity to 0.1 ml. oreton and also (a few days later) to 0.1 ml. 'Androfort' (another testosterone propionate preparation). On the same day we injected 0.1 ml. androfort into the skin of the pigmented area near the scar; after three days an area of necrosis measuring 0.3 × 0.2 cm. developed. Control injections with sesame oil and saline solution gave no reaction at all. After four simultaneous injections of oreton and antistin, the urticarial reddening subsided and the injections of the hormone were resumed without further reactions. The patient went steadily downhill, and she left the hospital on June 13 in an extremely grave condition. She died a few days later at home. Permission for necropsy was not granted.

It seems indisputable that the reddening and itching of the X-ray-pigmented area was an urticaria-like allergic reaction, and this was proved by the immediate response to anti-histamine substance and the successful desensitisation. Obviously the patient developed hypersensitivity to male sex hormone, though she had never before been treated with this. The sensitivity was not to a particular preparation of the drug, because the scratch test was positive both to oreton and androfort.

The fact that intracutaneous injection of 0.1 ml. androfort produced an Arthus-like necrosis in the X-ray-pigmented area favours the assumption that local (sessile) antibodies were present.

How did this sensitivity develop? The short interval between the start of treatment with male hormone and the development of the urticarial reaction is against the possibility of sensitisation to the injected hormone. It is, however, well known[1] that physical factors, such as X rays, may cause concentration of the circulating antibodies in the corresponding part of the skin; and the antibodies thus become localised. There are several possible sources of these circulating antibodies: (1) the provoking antigens might be breakdown products of the endogenous androgens, this biochemical process having been influenced by the X rays in the highly vascular

THE BILLROTH-I AND POLYA OPERATIONS FOR DUODENAL ULCER

A COMPARISON

J C Goligher
Ch M Edin, F R C S

P J Moir
M C, M B Glasg, F R C S

J H Wrigley
M B Edin, F R C S E

From the Professorial Surgical Unit, General Infirmary, Leeds

The Billroth-I resection is said by many to be followed by much less trouble from post gastrectomy symptoms than is the Polya operation, and for that reason it has been increasingly used in this country in recent years Many surgeons now regard this as the operation of choice for cases of gastric ulcer, to which it is, of course, especially suited The suitability of the Billroth I operation in cases of duodenal ulcer, however, is open to considerable dispute and surgical opinion is sharply divided on this issue To any surgeon who has had much experience of the operation, the objection that it will seldom be technically feasible when the ulcer lies in the duodenum itself will carry little weight, it is surprising how often a really high Billroth-I resection can be performed under such circumstances The criticism that a recurrence of duodenal ulceration is commoner with this technique than with the Polya method is less easily refuted, and reports are conflicting on this point

In view of this divergence of opinion, we have surveyed the late results of subtotal resection by Billroth-I and Polya techniques in the treatment of duodenal ulcer

Case-material

We analyse here all cases of duodenal ulcer admitted during the years 1948–54 inclusive for gastric resection, under the care of one of us (J C G) at St Mary's Hospital or of another of us (P J M) at the Leeds General Infirmary The survey comprises 312 patients (277 males and 35 females) whose ages ranged from 12 to 82 years, the majority being in their 4th or 5th decade Most of the patients had elective gastrectomy, but 20 had emergency operations for bleeding or perforated ulcers

Choice of Operation

Approximately half of the patients were treated by Billroth-I resection and half by Polya resection

The operations were performed by five surgeons of whom three performed Polya resections only and two started with Polya resections but at the end of 1949 adopted the Billroth-I method as the operation of first choice

In 8 or 9 cases early in the series Billroth I resection proved impracticable because of fixity of the ulcer or difficulty in bringing the stomach remnant and duodenum together after a high resection In these cases the operation was completed as a Polya gastrectomy, and was recorded as one of the Polya group

So far as possible with several surgeons taking part a uniform level of gastrectomy was maintained, with removal of at least three quarters of the stomach in all instances, including the Billroth-I cases

TABLE I—NUMBER OF BILLROTH-I AND POLYA RESECTIONS PERFORMED, FOR DUODENAL ULCER, 1948–54

Year	Billroth I	Polya	Both operations
1948		31	31
1949	2	27	29
1950	15	28	43
1951	30	25	55
1952	43	16	59
1953	23	12	35
1954	35	25	60
Total	148	164	312

Table I shows the numbers of both types of operation in the period under review Altogether there were 14 Billroth-I resections and 164 Polya resections In the earlier years relatively more Polya resections were done so the Polya group includes a higher proportion of patients followed up for a long time, this may have a bearing on the relative incidence of recurrent ulceration in the two groups

Losses from Series

Not all the patients were followed up, for, as table II shows, some died after operation, some died subsequently from causes unrelated to recurrent ulceration and some could not be traced

Operative Mortality

There were 12 deaths in the postoperative period, all due to leakage and peritonitis from a sutured duodenal stump or gastroduodenal anastomosis This gives an over all mortality-rate of 3 8% The mortality rate was roughly the same in both groups, there were 6 deaths in 148 patients treated by Billroth-I gastrectomy and 6 deaths in 164 patients treated by Polya gastrectomy, but the latter group included some cases with very adherent ulcers which had been rejected as unsuitable for the Billroth-I operation

TABLE II—DEATHS AT OPERATION, SUBSEQUENT DEATHS FROM UNRELATED CAUSES, UNTRACED PATIENTS, AND PATIENTS FOLLOWED UP

Type of operation	No of patients	No of deaths at operation	No of deaths from unrelated causes	No of untraced patients	No of patients followed up
Billroth I	148	6	1	9	132
Polya	*164*	*6*	*4*	*16*	138

Subsequent Deaths from Unrelated Causes, and Untraced Patients

5 patients died from other causes some time after leaving hospital

2 died from pulmonary tuberculosis one and two years after operation, 1 following prostatectomy four years after gastrectomy, 1 from an unspecified cause one year after operation, and 1 from cardiac failure five years after operation

Despite every effort, 25 patients could not be traced, owing either to a change of address or to their having left the country Several of these patients had been followed up for a short time before becoming inaccessible, but we have considered it best to exclude them from our assessment of the late results

TABLE III—RECURRENT ULCERATION IN ALL PATIENTS FOLLOWED UP

Type of operation	No of patients	Recurrences		
		Proven	Suspected	Total
Billroth I	132	14	6	20 (*15 1%*)
Polya	138	1	1	2 (*1 5%*)

The number of patients who died subsequently and the number who were untraced in each of the two groups were as follows Billroth-I, 1 death and 9 untraced, Polya, 4 deaths and 16 untraced

Follow-up

132 patients treated by Billroth I and 138 by a Polya gastrectomy were followed up (table II) We were interested in three aspects of the late results the incidence

Closing the average laceration took less than half the time eeded for suturing
It was economical
Pain caused by the removal of sutures was eliminated
There were no suture scars

Plastic tapes have been used to close about 100 major urgical wounds There have been no reports of a failure o secure an average or better than average closure, nd abdominal scarring is much less than when the skin s sutured

In a few cases plastic tape has been used to hold kin grafts in place No assessment of its merits can be made until further work is done, but at present this method looks promising

I will gladly send samples of the plastic tape, or further information about it, to any doctor willing to report critically upon his results

PAUL WILLIAMSON

MODIFIED QUECKENSTEDT TEST

SIR,—Dr Belton seems to be labouring under a misconception the Valsalva manœuvre does not replace the orthodox Queckenstedt test The former will show a significant rise of cerebrospinal fluid (C S F) pressure below the level of the lesion in cases of complete spinal block, as the raised intrathoracic and intra-abdominal pressures are transmitted to the spinal subarachnoid space through the vertebral venous plexuses Thus, if the Valsalva manœuvre is employed, the manometric diagnosis of partial or complete spinal block may be missed Incidentally, the rise of C S F pressure resulting from Queckenstedt's manœuvre occurs so quickly that it must, in part, be due to the sudden swelling of the intracranial veins, which displaces some C S F. into the slightly elastic spinal subarachnoid space

Leicester Royal Infirmary

H J GOLDSMITH

"MUNCHAUSEN'S SYNDROME"

SIR,—On reading Mr Mawson's letter (Jan 14) I recognised that the patient he described had been under my care in this hospital in November, 1955

He was admitted via our casualty department on Nov 23 on a stretcher, having been picked up in the city, suffering from ataxia followed by a blackout He gave a history of three mastoid operations and one for cerebral abscess within the past twenty two months, the last operation having been performed about four months previously He said that he was still "on parole" from a hospital in London He stated that he was an ex male nurse and ship's radio officer, and he was in Dublin to visit his fiancee

Besides some of the findings described by Mr Mawson we found definite slight papillœdema of the right disc, the right visual field was constricted generally Radiography showed almost complete loss of trabecular detail in the right mastoid region, a great deal of bone had been removed in each occipital region, and there were several trephine openings at a higher level on each side opacities resembling Michel clips were present

On the next day, his condition having improved and in view of suspected cerebral abscess possibly necessitating intracranial exploration, he was advised to return to London at once to the hospital where he had received his previous attention In order to expedite his return and as he had not got the full air fare, he was offered a sum of money Of this he took only part, but three days later the hospital had an inquiry from a city mission where he had been seeking further assistance This was the last we heard of him

I write these few notes in the hope that they may help the next colleague under whose care this patient comes

Adelaide Hospital
Dublin

R S W BAKER

SIR,—A seaman answering the description given by Mr Mawson reeled into casualty the other day, now presenting a marked cerebellar gait

His temperature of 101°F could not be shaken He was therefore admitted for observation but refused lumbar puncture Atkinson Morley Hospital had already heard of a man resembling this one, with multiple cranial scars on the right side and a right facial palsy, Princess Beatrice Hospital had dealt with him some time before Following an abrupt but punctilious interview by a physician the following morning, he took his own discharge stating he was Plymouth bound

Croydon General Hospital

F M MOORE

SPORADIC CRETINISM WITH GOITRE

SIR,—I was most interested by the views expressed by Dr McGirr and Dr Hutchison in their letter of Jan 14 It should however be pointed out that their statement "this [Stanbury et al [1]] was the first time that the spontaneous occurrence of diiodotyrosine in the peripheral blood was conclusively proved" is not entirely correct Benua and Dobyns [2] showed that small amounts of mono- and di-iodotyrosine are present in the blood of hyperthyroid and thyroid cancer patients after therapy doses of I^{131} Monoiodotyrosine, but not diiodotyrosine, was excluded as a radiation artefact Further, Benua and Dobyns [2] showed that neither of these compounds was produced from pure I^{131} labelled thyroxine, during their chromatographic procedures

ROSALIND PITT-RIVERS

OLD FOLKS AT HOME

SIR,—Sir Selwyn Selwyn-Clarke's address, from which you published extracts on Jan 14, suggests many ways in which old people can be assisted But it would be a pity if any reader drew the conclusion that all is well in this field—which is by no means correct

Although several ways and means of helping old people have been mentioned, it has not been made sufficiently clear that, good though these services are, they are not by any means to be found everywhere Indeed some of the examples given are isolated instances of a voluntary body endeavouring to meet a local need after a careful study of the problem It is a great pity that many of these services cannot be reproduced in more places, for I am convinced that the most important task of the voluntary bodies in this field at the present is the provision of properly integrated domiciliary services It is no easy task, for in many instances patience, skill, and devotion are required to a degree not possessed by all There are old people who are anti-social and "difficult" for whom often nothing is done until some near tragedy occurs True the health visitors and the district nurses do wonderful work, but in many places their time is so taken up with family work that they cannot attend to old people as they would wish, and there is, perhaps, less attention given to prevention than to cure I refer here not necessarily to medical treatment but to the support which can be given to old people, by a trained social worker, when they are beginning to deteriorate Too often nothing is done until the failing has gone too far to allow the old person to remain in a place where there is not constant supervision and this leads to an increasing demand for beds on the welfare and hospital services

There are a number of other points on which I should like to comment but there is one particular sentence which cannot fail to be noticed by general practitioners, social workers, and others "But when the nature of the illness or social conditions necessitate hospital care . the patient *will* (my italics) be removed, with his consent, to a hospital" How easy it sounds!

TABLE VI—POST GASTRECTOMY SYMPTOMS NOT DUE TO RECURRENT ULCERATION

Symptom	After Billroth I resection (% of 132 patients)	After Polya resection (% of 138 patients)
Postcibal epigastric fullness	45 4	39 8
Postcibal epigastric fullness with faintness and sweating, &c	15 1	10 8
Bilious regurgitation	9 0	15 2
Non bilious regurgitation and vomiting	6 8	5 0
Persistent weight loss of more than ½ st	20 4	15 9
Quick fatigue	11 3	15 9
Persistent diarrhoea	2 3	2 8

encountering a single instance of definite recurrent peptic ulceration in the stomach or elsewhere

In the present series the higher incidence of duodenal or stomal recurrences after Billroth-I resection than of jejunal ulceration after Polya gastrectomy is surprising in the light of the experimental work of Ivy and Fauley (1931), which gave good reason to believe that the susceptibility to peptic digestion of the duodenal mucosa is less than that of the jejunum On the other hand, the experiments of Mann and Williamson (1923) and others have shown the importance of the neutralisation of the gastric juice by the alkaline bile and pancreatic juice in the avoidance of jejunal ulceration after gastro intestinal anastomoses This factor of neutralisation probably explains why the Billroth I is less satisfactory than the Polya operation

After the Polya operation every drop of bile and pancreatic juice entering the alimentary tract must pass over the jejunal mucosa exposed at the stoma, and this part of the bowel is therefore afforded the fullest possible protection by neutralisation of gastric acidity But after a Billroth I gastrectomy, although there is certainly regurgitation of some bile and pancreatic juice from the second part of the duodenum into the first part and the stomach, a considerable proportion of these alkaline juices is presumably lost distally and cannot protect the duodenal mucosa adjacent to the anastomosis

Treatment of Recurrences

The single patient with a proven recurrence after a Polya resection was treated by vagotomy alone and subsequently had occasional dyspeptic symptoms At the present time, three years after the second operation, the patient is in fairly good health and no definite ulcer can be demonstrated radiographically The patient who had a suspected ulcer after a Polya operation was treated expectantly, he has had no further bleeding and only slight intermittent dyspepsia, and radiographic examination has been negative

13 of the 20 patients with proven or suspected recurrences after a Billroth-I gastrectomy had a further laparotomy After confirmation of the diagnosis, treatment consisted of vagotomy alone in 6 cases and conversion to a Polya type of anastomosis in 7 cases, in 2 of which a vagotomy was also performed All these patients have been seen recently, 4 of the 6 treated by vagotomy alone, and all of those whose anastomosis was converted to a Polya type, are very well 2 of the patients who underwent vagotomy continue to have some pain, as do the majority of the 7 patients treated by dietetic or expectant measures These experiences with vagotomy are of special interest because they suggest that the combination of vagotomy with a high Billroth-I resection in the treatment of duodenal ulcer would not provide a complete insurance against the development of recurrent ulceration

POST GASTRECTOMY SYMPTOMS NOT DUE TO ULCERATION

The frequency of the commoner post gastrectomy symptoms is shown in table VI There was very little difference between the frequency after the two operations, on the whole these results favoured the Pol method, but biliary regurgitation was undoubted commoner, and was probably more severe, after t Polya operation

THE PATIENT'S FUNCTIONAL STATE

The patient's functional state, and his capacity t work and enjoy life, is, in a way, the most importan point in assessing the results of any operation W employed a system of grading closely modelled on th recommended by Visick (1948)

Excellent meant that the result was perfect in every respe

Very good meant that the result was perfect in the eyes o the patient but that some symptoms were elicited by us T patients had largely forgotten about these symptoms, becau they were able to dispel them by minor adjustments to th diet and mode of life A persistent weight loss of up to 10 l was allowed for this category, but patients had to be complete fit for their previous work

Fair meant that the patient had fairly severe symptom but he considered that he was better off than before operatio Several of these patients had a persistent, severe weight los and had to seek lighter work

Unsatisfactory meant that the patient was not improve (Most cases of recurrence fell into this category)

Table VII shows the results in our two groups graded according to this system It shows a slight, but definite, superiority in the results of the Polya, compared with those of the Billroth-I, operation, the latter were especially marred by the large number of patients in the "unsatisfactory" category

TABLE VII—FUNCTIONAL RESULTS

Result	After Billroth I resection (no of patients)	After Polya resection (no of patients)
Excellent	50 } (75 0%)	70 } (89 8%)
Very good	49	54
Fair	13	10
Unsatisfactory	20	4
Total	132	138

Conclusions

The Billroth I resection, even when extensive, is an unsatisfactory operation for duodenal ulcer After this operation the recurrence rate (up to 17% on a three year follow-up) is much higher than that after the Polya operation (2%)

The Billroth I operation is no less likely than the Polya operation to be followed by post gastrectomy symptoms not due to recurrent ulceration, except biliary regurgitation

The functional condition of the patients after Billroth I resection is slightly worse than after the Polya operation

Sometimes the Billroth I method is not technically feasible, and if an attempt were made to enforce it as routine in all cases of duodenal ulcer the operative mortality might well increase

We see no reason whatever for using the Billroth I resection as a primary operation for duodenal ulcer when there is available one so excellent as the Polya, but we admit that for the occasional very severe case of bilious vomiting after Polya gastrectomy for duodenal ulcer it may be justifiable to convert the anastomosis to a Billroth I type and accept the increased risk of recurrent ulceration in order to eliminate this incapacitating symptom

CERVICAL VERTIGO

SIR,—It is most interesting to see the different opinions n the ætiology of paroxysmal vertigo, the latest contribution to which is made by Dr Ryan and Dr Cope Dec 31) under the above heading

I myself made a small effort to solve this problem[1] have also observed that pain stimuli in the head and eck, for example, may elicit attacks of vertigo by bending he neck, but not pain alone except in patients with migraine In these particular cases of vertigo I have always found an imbalance of the masticatory apparatus, of which the muscles and joints and also the trigeminal nerve are involved, owing to a faulty bite The vertigo vould be a reaction of the ear to a physical irritant, and I suggested[1] that the paroxysm is caused by myoclonus of the middle ear muscles

In addition to the instability of the sensory organ in the semicircular canals in these cases, there is also an affection of the cochlea This may be fluctuating or permanent, subjective and/or objective, and perceptible by audiometric examination The lesion does not seem to be cervical

Bergen Kommune sykehus
Bergen Norway
H MYRHAUG

SIR,—In reply to Mr Wilmot's comments (Jan 7) on our article (Dec 31) by aural investigation we meant that audiometry and caloric testing were carried out in addition to clinical examination The question of cervical sympathetic involvement in the quoted cases was discussed in the paper, and though we considered it a possible mechanism our reasons for favouring the alternative explanation were given The presence of cervical disease and vertigo does not of itself signify that the two are related What we wished to show was that there is a characteristic clinical picture by which cervical vertigo can be diagnosed

ANÆSTHESIA FOR CÆSAREAN SECTION

SIR,—In an earlier letter[2] I referred briefly to anæsthesia by hexobarbitone, suxamethonium bromide, and nitrous oxide for cæsarean section I have received many inquiries about the technique

Patients come to the theatre with a Ryle's tube in situ, premedicated with gr $^{1}/_{150}$ atropine sulphate The stomach is aspirated immediately before induction

When the patient has been towelled 0 5 g hexobarbitone is given intravenously, followed immediately by 60 mg suxamethonium bromide ('Brevidil M') through the same needle, and the surgeon makes his incision

While the incision is being made the patient's lungs are gently inflated with a mixture of nitrous oxide (75%) and oxygen (25%) until the relaxant has taken effect Then the patient is intubated and the nitrous oxide/oxygen mixture is continued, a Gordh needle is put into a vein on the back of one hand, and the forearm flexed to bring the needle within easy reach of the anæsthetist

Once the delivery has started the nitrous oxide is cut off and the patient's lungs are flushed with pure oxygen until the cord is cut when the cord is separated the patient is put back on the former nitrous oxide/oxygen mixture, and a further 0 5 g hexobarbitone is given through the Gordh needle—by means of which ergometrine has already been given at the time of delivery

Usually the effect of the suxamethonium bromide has worn off by the time delivery takes place, but sometimes either the surgeon is quicker than usual or the action of the relaxant persists unusually long, and the mother is apnœic when the child is born, but on no occasion has the child's respiration been depressed, and it would appear that the suxamethonium bromide is "lost" in the placenta

I have never seen maternal or fœtal respiration depressed by hexobarbitone, and I prefer this technique to any other, including spinal anæsthesia

Gloucester Royal Infirmary
J SHEGOG RUDDELL

UTERINE DYSFUNCTION DURING LABOUR

SIR,—I have suggested[1] that uterine dysfunction may be related to the patient's personality, and have described a "dysfunction temperament" characterised by suppression or repression of feelings of tension, so that little or no overt anxiety is shown Women with this temperament are reserved and difficult to know, they have a slight tendency to develop peptic-ulcer symptoms, and they have a bias towards rigid and conventional forms of behaviour

This bias was deduced from the results of the Minnesota Multiphasic Personality Inventory,[2] which was completed by most of the patients I investigated It was discovered that 45% of the dysfunction group had high "lie" scores compared with 20% of the control group, the difference being significant at the 2% level

The "lie" score is based on the answers ("true" or "false") to the following 15 questions which are so devised that, if answered honestly, they place the patient in a socially unacceptable light

1 Sometimes, when I am not feeling well, I am cross
2 I would rather win than lose in a game
3 I get angry sometimes
4 I do not like everyone I know
5 Once in a while I think of things too bad to talk about
6 Once in a while I put off until tomorrow what I ought to do today
7 I gossip a little at times
8 I sometimes laugh at vulgar stories
9 My table manners are not quite as good at home as when am in company
10 I do not always tell the truth
11 I do not read every editorial in the newspaper every day
12 If I could get into the cinema without paying and be sure I was not seen, I would probably do it
13 At times I feel like swearing
14 Sometimes at elections I vote for a man about whom I know very little
15 I like to know some important people because it makes me feel important

If a patient answered "false" to 7 or more of the 15 questions, her "lie" score was regarded as significantly high, that is to say, she tended to deny in herself venial faults which we all possess, but which we dislike to admit to other people lest we fall in their estimation

In a subsequent investigation the 15 items of the "lie" scale were incorporated in an inventory with 65 other items dealing with pregnancy and with anxiety-producing situations, and the inventories were given to 900 consecutive primigravidæ who attended the Aberdeen Antenatal Clinic during the latter part of 1954 and the first half of 1955

The test was administered by the health visitor in charge of the clinic and the completed inventories were sent to me

WATER DEPLETION

Common Cause

Diminished intake in weak or ill patients, especially after operations, and in coma

Note—Normal water requirements are about 2 5 litres a day (average minimum 2 litres) On a normal diet 1 5 litres a day is taken as fluid, and 1 litre is contained in the food. Therefore, if no food is taken, fluid intake must be increased by 1 litre a day Water is required to replace insensible loss (about 1 litre) and to provide 1 0–1 5 litres for daily urinary excretion Normal water intake must be maintained *in addition to replacement of any abnormal fluid loss* Normal saline solution, for instance, does not satisfy water requirements

ELECTROLYTE DEPLETIONS

Na and Cl are mainly involved, and to a lesser extent K

Body fluid containing electrolytes ("electrolyte fluid") may be lost in the following ways

Common Causes

Vomiting
Gastric suction
Intestinal or biliary drainage
Diarrhœa

Rarer Causes—Via the urine in

Diabetic ketosis and coma
Continued use of mercurial diuretics, and repeated paracentesis or acupuncture, especially in association with a low Na intake
Diuresis following anuria
Untreated Addison's disease

MANAGEMENT OF DEPLETIONS

(1) *Object* the correction of existing depletions as soon as possible and the prevention of threatened depletions

(2) *Criteria of success* the maintenance of a normal urine volume of 1 0–1 5 litres per day, with normal urine and plasma electrolyte levels (see notes F and J)

(3) Water depletion is corrected by giving water in excess of normal requirements

(4) Since electrolyte depletion is mainly due to loss of Na and Cl in approximately isotonic fluid, correction is, in the first instance, by replacement with isotonic NaCl (normal saline) solution, the volume required being the same as the volume of body-fluid lost (see para 5 and note G) Although the composition of the replacement fluid will not be exactly the same as that of the fluid lost, the necessary adjustment will usually be made by the kidney (see notes C and D)

Potassium depletion usually appears when a considerable volume of body-fluid has been lost and intake is inadequate Intravenous isotonic solutions of potassium salts should, however, *not* be used for replacement as these are too concentrated The solution of KCl containing 40 m eq of K per litre should be used (see para 5 and note E)

Electrolyte and water depletions may occur together, in which case measures in paragraphs (3) and (4) should be combined

(5) *Routes of Administration of Principal Fluids*

	Mouth or gastric tube	*Intravenous*	*Per rectum*
Water replacement	Tap water 5–10% dextrose solution	5% dextrose solution	Tap water
Electrolyte replacement		Normal saline solution* (155 m eq of Na and Cl per litre) Sodium lactate solution* (155 m eq of Na per litre) Potassium chloride solution* with 3 5% glucose (40 m eq of K per litre, see note E)	
"*Maintenance solution*"		½ normal saline solution* with 4% dextrose (see note B)	

* These solutions can also be given by mouth or gastric tube in appropriate cases (see note K)

In some cases it may be possible to give NaCl and KCl crystals by mouth in capsule form, provided water intake i increased proportionately (see note K)

For the correction of an existing water depletion 1–4 lit of fluid is usually required according to the severity of th depletion For the correction of an existing electroly depletion 1–8 litres is usually required (para 7)

(6) *Use of Chart*

The chart is designed for a period by period comparison o water and electrolyte fluid intake and output with urine an blood analyses

Electrolyte fluid—"Electrolyte fluid loss" in any o period should be directly compared with "electrolyte flu replacement" for the same period The total under the two headings should balance volume for volume (e g, 1 lit from biliary drainage should be replaced by 1 litre of norm saline solution), provided that there is no pre existing electrolyte depletion If there is already a depletion, it should b corrected at the same time as current losses are being replaced the total under "electrolyte fluid given" remaining muc larger than the total under "electrolyte fluid loss," until th pre existing depletion is made good

Water—No attempt need be made to obtain a similar bal ance with water The total volume of water given should b that necessary to obtain a normal urine volume of 1 0–1 litres a day (see notes F and J) The actual volume of urin passed in a period is charted under "urine analysis"

Analyses—Urine and blood analyses are charted alongsi the electrolyte and water intake and output data for eac period

(7) *Treatment of Existing Depletions*

In a fresh case the nature and extent are estimated, b recognition of the cause, the clinical findings, and a *complet* blood and urine analysis as detailed in the chart (urine bein obtained by catheter if necessary)

(*a*) Enter biochemical findings in period 1 of chart, and wri estimated requirements for period 2 (these will fall within th limits given in para 5) on the back of the chart, bottle b bottle These are initialed by the nurse as they are give (Note that details entered on the *front* of the chart are for th period just elapsed, and that fresh orders entered on th *back* of the chart are for the period just begun With a ne *case, therefore, the first orders are entered on the back* period 2)

(*b*) At the end of each period the patient's bladder i emptied, and *all* urine passed in the period is sent with a bloo sample to the laboratory for analysis (see note H) Enter th results of the analyses in period 2, *together* with total (obtained from nurses' fluid chart) for electrolyte fluid los electrolyte fluid replacement, and water intake From th information, and from the laboratory analyses, it will b apparent to what extent existing depletions have been mad *good, and what further losses* have occurred during th period Order appropriate solutions on back of chart for nex period, including normal water requirements

(*c*) Discontinue the above régime when depletions hav been corrected, and source of depletion is under control *Continue thereafter with maintenance solution* (note B) unti normal intake by mouth can be maintained Over treatmen is dangerous

(8) *Treatment of Threatened Depletions* (due, for example, t postoperative drainage from fistulæ, gastric suction, diarrhœa *or vomiting, but where there is no* pre existing depletion)

(*a*) Request complete blood and urine analysis Estimat volume of fluid likely to be lost from body during next perio and order necessary replacement solutions, *including* wate requirements for the period (*It may be necessary to revie the estimate as period proceeds*)

(*b*) At the end of period, empty bladder, send all urine and specimen of blood to laboratory for analysis Enter the analyses on chart, with totals for electrolyte fluid loss, electro lyte fluid replacement, and water intake Review all finding and *order appropriate solutions for next* period on back chart, including water requirements

(*c*) Continue this procedure until source of depletion under control

Notes

(A) Twenty four hour periods of controlled treatment a usual, but in a severe depletion twelve hour periods are ofte necessary at the start All information for one period shoul be obtained before prescribing for the next period

(B) 2 5 litres of the maintenance solution a day will cove both water and electrolyte requirements where electroly

After abolition of the vomiting, by direct suggestion, he patient's excessive salivation apparently symbolised he still present need to rid herself of the fœtus Later eports stated that she was well

"There are many things, the knowledge of which is of little or no profit to the soul" [5]

London, W 1 GORDON AMBROSE

POLIOMYELITIS VACCINE

SIR,—Extensive use of this vaccine in this country is now proposed It may seem a presumption to raise any question when it has apparently such eminent sponsorship, but, as one of the persons who will be concerned with the actual administration of this vaccine, I cannot help feeling some uneasiness It appears that the degree of protection given is not certain and also its duration We are assured that the vaccine is fully safe, but one cannot but recall that poliomyelitis vaccines in the United States last year had disastrous consequences

When this vaccine comes into use it will mean that three materials are being used in this country whose efficacy is uncertain and whose safety is open to doubt

The first is B C G, which is being used on an ever increasing scale although there is as yet no proof that it is of any value, while there is actual certainty that in a proportion of cases it produces damage of greater or less amount

The second is whooping cough vaccine, also being used on a large scale although we have not yet been given any statistics to show its value—if any One had understood that a factual report on whooping cough vaccine was to be published, but so far all that seems to be available are statements as to "clinical impressions" Many of us are not particularly interested in clinical impressions we require figures

Now this poliomyelitis vaccine is to be brought into general use without, to my mind, satisfactory evidence of its efficacy and safety

Although poliomyelitis rightly causes great concern, both because in a small proportion of cases its consequences are disastrous and because it is a disease for which we have no specific treatment, nevertheless a sense of proportion is called for Even in the worst years we have yet experienced, although the number of cases of poliomyelitis infection has amounted to several thousands, they represent a minute proportion of the population at risk, and the number of cases in which death or paralysis has occurred has been small in proportion to the population Is it proper to administer a vaccine of doubtful potentialities to the child population at large to meet so small a risk? I agree that the individual parent, faced with the death of a child from poliomyelitis or with a paralysed child, will rightly regard this as a very great tragedy, but I do question whether the facts justify us, as yet, in undertaking a mass vaccination campaign In saying this I would like to make it clear that I am by no means an anti vaccinationist I am an enthusiastic supporter of immunisation against diphtheria Here the position is rather different, since we are dealing with the use of a chemical substance and not with an organism living or dead I am also a firm believer in the value of anti smallpox vaccination and yellow fever inoculation But I do think it is not unreasonable to suggest that poliomyelitis vaccines are as yet only in the experimental stage, and I do question whether we have any right to carry out a large scale experiment which may have serious consequences I would certainly hesitate myself, in the present state of knowledge, to give myself or my children this vaccine I think that similar doubts may well be felt by quite a proportion of medical practitioners, and I therefore raise this matter to see if we may have some indication in your columns as to the extent of the doubts felt about this and also whether any convincing evidence can be brought forward to settle these doubts

All this, I should make it quite clear, is a purely personal expression of opinion

Accrington, Lancs R C WEBSTER

Obituary

WILSON HAROLD HEY

M B Manc, F R C S

Mr Wilson Hey, consulting surgeon to the Manchester Royal Infirmary, died on Jan 15 at the age of 73 He was a general surgeon with a strong bias towards urology and he will be remembered particularly for his work on prostatic carcinoma and for the method of prostatectomy that he devised

He was born in Colne, which lies in the heart of Lancashire, and he early showed the determination and stubborness said to be characteristic of the palatinate He entered Manchester University with a leaving scholarship from Burnley Grammar School, and he proved himself an outstanding student, with an original mind His retentive memory and capacity for work served him well, and he won many prizes, medals, and scholarships After graduating M B in 1905 he held house-appointments at the Manchester Royal Infirmary, later becoming resident surgical officer and surgical tutor He was awarded the Tom Jones Research scholarship in surgery and in 1908 he took the F R C S Shortly before the outbreak of war in 1914 he was appointed to the honorary staff of the Royal Infirmary, but almost at once he left Manchester to serve as a surgical specialist with the rank of major in the R A M C For his services to French soldiers he was appointed a chevalier of the Legion of Honour

Schmidt Manchester

On his return to Manchester after the war Wilson Hey's surgical technique and his energy soon gained him a large practice In 1919 he was appointed to the staff of the Christie Hospital and he was one of the first surgeons to use radium He also joined the staff of the Ancoats Hospital, and the Manchester Children's Hospital He was lecturer in clinical surgery at the university he was an interesting and stimulating teacher and students flocked to his outpatient department, for he knew how to pinpoint a principle with an unbelievable but also unforgettable anecdote

Despite his large private practice and his hospital and teaching duties, his original turn of mind and energy obliged him to make time for research Urological surgery had long been his chief interest, and he showed that, in his hands at least, the emergency removal of the prostate gland was a safe proceeding His "aseptic" operation was a transvesical prostatectomy (preceded by twelve hours' chemotherapy) in which the trigone was excised and the bladder afterwards closed He was insistent that "technique and route are merely the handmaidens of asepsis in any operation," and he urged that a catheter should never be used before prostatectomy Latterly, he was also investigating the use of hormones in breast and prostatic cancer and shortly before his death he was putting the finishing touches to his record of his results in cancer of the breast for the last thirty years An old patient had left him a large sum of money to establish a hormone research department at the Christie Hospital and he was preparing the plans for this project

---

[5] Thomas à Kempis De Imitatione Christi Chapter 2

Laboratory Examinations

The erythrocyte sedimentation rate (E S R) was raised, ranging from 70 to 120 mm in the 1st hr (Westergren) Leucocytosis ranged from 11,000 to 20,000 per c mm , with a shift to the left in the differential count Blood-cholesterol and serum-protein levels were within normal limits Throat swabs yielded micro organisms belonging to the usual flora of the upper respiratory tract (non-hæmolytic streptococci, *Neisseria catarrhalis*, &c) Radiography did not reveal either compression of the trachea or substernal goitre Electrocardiography was normal The basal metabolic rate (B M R) at the time of admission was raised in all the cases, ranging from +13% to +55% The uptake of radioactive iodine by the thyroid gland ranged from 0 to 13%, and its excretion in the urine was correspondingly increased

Treatment

4 of these patients had received penicillin, streptomycin, or chloramphenicol before admission without effect

Two days after admission 3 patients were treated with oral cortisone 50 mg daily Within twenty-four hours after the administration of cortisone the temperature became normal, the pain subsided, and the patient's general condition improved considerably Treatment was continued with decreasing doses up to four weeks No immediate or late relapses were observed

2 other patients were treated with corticotrophin gel 20 mg twice daily The immediate effect of corticotrophin was as beneficial as that of cortisone, but 1 of the corticotrophin-treated patients had two relapses when the dose was reduced Subsequent increase of the dose readily suppressed the signs again No late recurrences were observed

The 6th patient received no treatment, because she had been admitted to hospital in the sixth week of her disease, when she had recovered spontaneously

The E S R was gradually lowered within three weeks in the patients treated with cortisone and corticotrophin gel The leucocyte count returned to normal during the same period

The B M R and the uptake of radioactive iodine were studied in 3 patients three weeks after the institution of therapy, and the results were similar to those obtained at the time of admission

These examinations were repeated in 4 patients four to fourteen months after their discharge from hospital In 3 of them normal values were obtained, but in the 4th a slightly increased uptake (66%) of radioactive iodine was noted The 2 remaining patients were not available for follow-up

Discussion

All 6 patients reported here were women, aged 35–64 The incidence of non-suppurative thyroiditis in women of this age-group has already been noted (Thorn and Forsham 1952, Williams 1950)

During the acute stage the clinical signs and symptoms indicated thyrotoxicosis It has been suggested that these signs may be due to the escape of thyroglobulin from the disrupted acini into the blood stream (Crile 1952)

4 cases were followed up for four to fourteen months In none of them did clinical symptoms and signs of either thyrotoxicosis or myxœdema appear Repeated examinations of B M R were normal, and the uptake and excretion of radioactive iodine was normal in 3 patients and slightly increased in the 4th This finding is in agreement with the cases observed by Robbins et al (1951) for two and a half to ten months On the other hand, McConahey and Keating (1951) reported that myxœdema developed in 6 of 21 cases of thyroiditis It is not clear whether the diagnosis in these cases was confirmed by a study of the uptake of radioactive iodine or by determinations of protein-bound iodine The question whether either corticotrophin or cortisone can prevent the development of myxœdema in these cases is thus left unanswered A longer follow up and larger numbers of patients are needed to clear this up

Krupp et al (1951) reported the prompt effect of cortisone in non-suppurative thyroiditis, and numerous investigators have confirmed this (Crile 1952, Crile and Schneider 1952, Benjamin 1955, Kraft and Wolf 1955) In the present 5 cases treated with either corticotrophin or cortisone the symptoms and signs disappeared rapidly In 1 of these patients two relapses occurred concomitantly with a decrease in the dosage of corticotrophin , but a prompt response was obtained by increasing the dose again Similar relapses were reported by Teitelman and Rosenberg (1953)

Several attempts have been made to explain the beneficial effect of corticotrophin and cortisone in non suppurative thyroiditis Most workers ascribe the rapid clinical improvement to non specific alteration of the tissue response to inflammation (Crile 1952, Kraft and Wolf 1955), but the exact nature of this effect has not yet been elucidated

Summary

6 cases of subacute non-suppurative thyroiditis are described In 5 of them the administration of either corticotrophin or cortisone had a prompt beneficial effect on the clinical symptoms and signs

The uptake of radioactive iodine by the thyroid gland was close to zero in the 5 cases in which it was studied, and returned to normal in the follow-up period of four to fourteen months

Neither late recurrences, nor myxœdema, nor thyrotoxicosis were seen in these cases

We wish to thank Prof M Rachmilewitz for his helpful suggestions, and Dr J A Stein for the determinations of uptake of radioactive iodine

VACCINIA VERSUS POLIOMYELITIS?

D P MacIver
M C , T D , M D Edin , D P H
MEDICAL OFFICER OF HEALTH, WALTON AND WEYBRIDGE URBAN, CHERTSEY URBAN, AND BAGSHOT RURAL DISTRICTS, SURREY

Since 1947 I have been investigating, by personal visits and by observation in hospital, all cases of acute poliomyelitis occurring in the three county districts for which I act as medical officer of health Early in this work I formed an impression that poliomyelitis seldom attacks children who have been vaccinated against smallpox during the previous few years , and last autumn's outbreak has provided me with clearer evidence that this is so

Observations

In the three districts, which have a total estimated population of 87,340, the number of children born in 1946–54 was 11,842 Of these a small majority (53%) were vaccinated * , and one would therefore expect to reparation of the antigen was not generally understood, and he wide use of the Dreyer technique designed for H agglu ination influenced many workers to allow their culture of roteus OX to revert to the OH form and thus to lose pecificity By slavishly following Felix s instructions I was aved from this error Later I came to know him personally, e corresponded much when I was overseas, and there were ontinual reminders of the clarity of what he wrote He ook infinite pains to express himself clearly in correct English

---

* In this paper the word ' vaccinated " means vaccinated against smallpox

'Felix travelled widely and enjoyed travel He knew eminent bacteriologists in most countries, and he liked to visit them in their laboratories Because of this he was a mine of information about most of the personalities in the bacteriological world A hard master he demanded much of his assistants, but he himself was a slave to his own work He believed in the importance of his own department, but he also understood the need for a sense of proportion in a large institute He was not given to great social activities, but he was a thoughtful and generous host, and a loyal and powerful friend, capable of great charm and kindness, and he had a gentleness that sometimes surprised those who did not know him well"

Dr Felix stayed at Colindale as director of the Central Enteric Reference Laboratory until his retirement under the age-limit in April, 1954 Still fully active, and working under a special grant for two years, he was given accommodation at the Lister Institute to complete unfinished work There he continued at full tempo until the very end

ARCHIBALD FRANCIS WRIGHT

M C, M B Edin

Dr A F Wright, pathologist to the Coventry and Warwickshire Hospital from 1924 until his retirement in 1951, has died at the age of 72

He was born at Southport and educated at Monmouth Grammar School, Edinburgh Academy, and the University of Edinburgh, where he qualified in 1906 In the same year he was appointed to the staff of the Monmouth Hospital In 1910 he became bacteriologist and consultant clinician for venereal diseases to the Staffordshire County Council During the 1914–18 war he served with the R A M C as bacteriologist He was mentioned in despatches and awarded the Military Cross In 1920 he visited the West Indies as a member of the Medical Commission to Combat Venereal Diseases

After his demobilisation he decided to specialise in clinical pathology, and he served as pathologist, always with a strong clinical bias, on the staffs of hospitals in the West Midlands, finally coming to rest in Leamington as pathologist, first to the Warneford Hospital, and in 1924 to the Coventry and Warwickshire Hospital He was a far-sighted and competent organiser, and it was thanks to him that between the wars the authorities of the Coventry and Warwickshire Hospital and the Coventry Borough Council were persuaded to set up a joint laboratory service, with a laboratory within the hospital Such an arrangement is now commonplace, but at that time such close cooperation between a voluntary hospital and a municipal health authority was unusual The joint laboratory service proved of the greatest benefit both to the hospital and to the health service of the borough In 1938 he started a blood-transfusion service based on the laboratory, and at the outbreak of the late war it had already enrolled over 10,000 donors He was a founder member of the Association of Clinical Pathologists, and he served on the advisory committee in pathology of the Birmingham Regional Hospital Board from its inception until his retirement

S C D, to whom we are indebted for some of this information, adds

From the beginning of his medical career Dr Wright was imbued with a sense of the importance of the laboratory in clinical medicine, at that time practically unrecognised in British medical practice It may truly be said that he introduced clinical pathology into the West Midlands For some time before and since his retirement, his health was not good, and latterly few of his colleagues had seen much of him It is a sign of their affectionate regard that to them he was always "Pop" With his passing, a figure that had become and will remain traditional has disappeared

CARL EISINGER

M D Vienna, L R C P E

Mr Eisinger, ear, nose, and throat surgeon to the West Middlesex Hospital, Isleworth, died in London on Jan 14 He was born in Vienna in 1895, and he qualified there in 1920 He worked first at the Institute of Embryology, where he became lecturer under Prof H Fischel and published papers on the artificially induced division of unfertilised ova in mammals and the extirpation of the inner ear in amphibia He later turned to ear nose, and throat work and was elected to the staff of the Vienna university hospital under the late Prof H von Neumann He was appointed Dozent in 1934 Four years later, when Austria was taken over by the Nazis he was forced to leave Vienna

When he arrived in England he expected to go to the United States, where he had been offered a post at St Louis, but when he was appointed postgraduate lecturer at the Metropolitan Ear, Nose, and Throat Hospital, he decided to remain in this country In 1910 he took the Scottish conjoint qualification Later he was appointed to the staffs of the Metropolitan Ear, Nose and Throat Hospital and the West Middlesex Hospital During the late war he was honorary lecturer at St George's Hospital Medical School

After the war Eisinger was twice approached on behalf of the University of Vienna, with a view to his taking up the chair in otorhinolaryngology there, but he preferred to stay in the country of his adoption

R S G writes

'I had the good fortune to meet Carl Eisinger over twenty five years ago in Vienna when he was senior assistant in Neumann's department, where he taught many hundreds of postgraduates from all parts of the world In 1938 he came to this country and was welcomed by a large number of otologists who had attended Neumann's clinic, and was induced to stay in this country He was a man of culture, who lived for his profession and love of people, and, with a wide knowledge of his specialty, which he practised with courtesy and dignity, he soon built up a large consulting and hospital practice He was a jovial companion and a most loyal colleague with high ideals In discussion and in committee he freely expressed his opinion with foresight and wisdom By his death we have lost an otologist of high standing with a great international reputation"

Mr Eisinger leaves a widow and a son, Dr George Eisinger

HORST OERTEL

M D Yale

Professor Oertel, who died at the age of 84 in London on Jan 9, was one of the last links between Virchow, the father of cellular pathology, and pathologists of the present time He was Strathcona professor of pathology at McGill University from 1919 until 1938, and during his time he was largely responsible for the building and development of the pathological institute there When it was opened in 1924, A E Boycott travelled from England to give the inaugural address

Oertel was born at Oberlossnitz, near Dresden, and educated at schools at Plaven and Meissen He took his medical degree in the United States, and after graduating M.D at Yale University in 1894 he returned to Germany to begin his postgraduate study of pathology in Berlin He found the medical school there overcrowded, and though he appreciated the teaching of men like Virchow, von Leyden, Gerhardt, and von Bergmann, he moved to Wurzburg, where he acted as junior assistant to Rindfleisch and Borst It was while working at Wurzburg that Oertel decided that if he was to follow an academic career it was essential to have a preliminary training in philosophy, logic, and biology Wundt at Leipzig was attracting students and research-workers poliomyelitis than those of the less well to do. The fact that, among children contracting poliomyelitis at 5–15 years of age, there was no difference between the vaccinated and the unvaccinated supports the view that social and geographical differences are not the explanation of the findings in the younger children.

4. The fourth possibility is that, at any rate in young children, vaccination against smallpox reduces the likelihood of developing paralytic poliomyelitis within the next three years. Why it should do so is not obvious; for, though postvaccinal encephalitis and polio encephalitis resemble one another clinically, I am informed that no serological relationship between vaccinia and poliomyelitis viruses has been recognised. Hence if there is, as I have postulated, an inverse relationship between vaccination and the incidence of paralytic poliomyelitis, it will require further explanation.

Summary and Conclusions

In 1946–55, in a mainly urban area, with a population of 87,000, where a small majority of children are vaccinated in infancy, there were 21 cases of paralytic poliomyelitis in unvaccinated children under 5 years of age but only 4 in their vaccinated coevals. Of the 19 children under 3½ years old who contracted the disease 17 had never been vaccinated and 1 had been vaccinated only four days previously.

The evidence of this small series suggests an inverse relationship between vaccination and paralytic poliomyelitis in young children. The potential importance of such a relationship makes it desirable that its existence should be proved or disproved, for which purpose equally detailed examination of larger material will be necessary.

I have to thank the parents of all the children for their help and for the information they gave me so willingly, sometimes under difficult and distressing circumstances.

NAPHTHALENE POISONING

E. Gidron
M.D. Rome
DEPUTY CHIEF

J. Leurer
M.D. Zürich
ASSISTANT

DEPARTMENT OF MEDICINE OF THE SHA'ARE ZEDEK GENERAL HOSPITAL, JERUSALEM

Since the introduction of naphthalene in 1841 by Rossbach as an internal antiseptic in typhoid fever and in 1842 as an anthelmintic and adjuvant in dermatological conditions, many cases of intoxication with this substance have been reported—mainly as side-effects of therapy. Industrial naphthalene fume poisoning, chiefly with skin manifestations (Touraine and Ménétrel 1934, Fanburg 1940) and especially naphthalene cataract (Bouchard and Charrin 1886, Michail and Vancea 1927) have also been often reported and investigated.

The fact that, though naphthalene is widely used, only 9 cases of poisoning have been reported since 1947, suggests that this condition often goes unrecognised. Perusal of standard textbooks of medicine, pharmacology, and toxicology supports this impression, for naphthalene intoxication is described in but few of them, and some current textbooks still recommend the therapeutic use of naphthalene.

We therefore report here another case of attempted suicide with naphthalene, review previous publications, and present a comprehensive clinical and pathological picture of "moth-ball anæmia" (*Lancet* 1949). It is to be hoped that naphthalene poisoning will find its way into the new editions of textbooks of medicine, and that naphthalene will be dropped from the modern therapeutic armamentarium.

Case-report

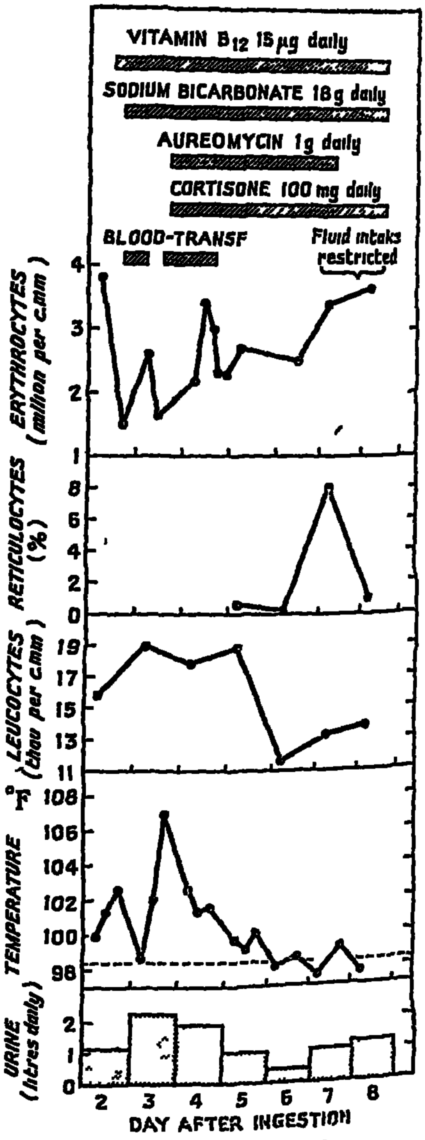
A girl, aged 16, an immigrant from Kurdistan, was admitted to the medical department of this hospital on Dec. 2, 1954, with the history of having taken, 24 hours earlier, about 6 grammes of naphthalene in order to commit suicide. For the 12 hours preceding admission she had increasingly suffered from vertigo and generalised abdominal pain, and had passed four yellow stools. In the evening a physician had given her an emetic, whereupon she had vomited twice.

Dec. 2.—On admission she was in good physical and mental state, not especially pale, and not icteric. The only abnormal findings at physical examination were tenderness of the abdomen, especially to the left of the umbilicus, and marked tenderness in both loins. Liver and spleen was not palpable. Temperature was slightly raised. The girl was quiet but alert.

Dec. 3.—Next morning she complained solely of vertigo, but during the afternoon she became pale and apathetic, complaining of vertigo and of pain in both kidney regions. The red-cell count, which had been 3,500,000 per c.mm. in the morning, had decreased to 1,500,000. The urine, which had been bright-brown (negative for naphthalene and naphthol) in the morning became dark-brown, although benzidine negative. A blood-transfusion (800 ml.) was given, and sodium bicarbonate 3 g. 4-hourly was administered to keep the urine alkaline and to reduce the risk of renal damage from deposition of hæmoglobin.

Dec. 4.—She was now strongly icteric. In the afternoon she complained again of vertigo, and euphoria was noted. Her temperature, raised since admission, reached its peak (41.6°C, 106°F) that evening, and treatment with chlortetracycline (aureomycin) 1 g. daily was started. The red-cell count was 2,000,000 per c.mm. in the morning, but dropped to 1,050,000 at noon. Another blood-transfusion (800 ml.) was given and a constant drip transfusion was set up. The blood-plasma was cherry red, and the urine port-wine coloured and benzidine positive. In an attempt to stop the hæmolysis treatment with cortisone 100 mg. daily was started.

Dec. 5.—The red-cell count was 3,400,000 per c.mm. at noon and 3,000,000 in the afternoon (when the blood-transfusion was stopped). In the evening and during the night the count was 2,300,000, at which value it became steady. From the afternoon of Dec. 5 onwards the patient started to recover also subjectively. The destruction of red cells, on Dec. 4 and 5, was at a rate of 1,000,000 per c.mm. every 3 hours.



A case of naphthalene poisoning

Notes and News

POISONS RULES

AMPHETAMINE and dexamphetamine have lately been added to the fourth schedule of the Poisons Rules[1] Accordingly these drugs may now be sold by retail on prescription only

VISITING CHILDREN IN HOSPITAL

THE Ministry of Health, which has more than once urged hospitals which admit children to allow frequent visiting[2] has again brought this need to the notice of hospital authorities[3], and it expresses the hope that existing arrangements for children visiting their parents in hospital will be extended

The Ministry finds that only 10% of hospitals admitting children now restrict visiting to one day a week or less, such hospitals include 28 which still prohibit all visits except in emergencies The Standing Medical Advisory Committee has reported to the Minister that at infectious diseases hospitals frequent visiting, subject to safeguards, can be allowed, and indeed at some is already being allowed The safeguards include a sufficiency of single bed wards, enough nursing staff to supervise visiting parents, the wearing of protective clothing by visitors, and the application to them of routine measures for preventing the spread of infection, the total prohibition of visitors in the case of some diseases, and the limitation of visiting in general to parents and guardians Many hospitals which do not allow daily visiting give as the reason the undesirability of admitting visitors on days when there are operating sessions, but the committee suggests that there is no general reason why all visiting on such days should be prohibited The visiting of children admitted for tonsillectomy may not be necessary where the child's stay is for twenty four hours or less, but it is undesirable for a child to be denied visitors if it is to be in hospital for three or four days Daily visiting in mental deficiency and other long stay hospitals is desirable, even though this may interfere with the hospital's routine Daily visiting should be allowed even in remote hospitals, so that parents can at least choose the most convenient days, and it would be helpful if these hospitals arranged for the shelter and refreshment of visitors and for accommodating other children whom the parents may be obliged to bring with them Where children have to be admitted to wards for adults there is no good reason for prohibiting daily visiting, even if this arrangement differs from that for the visiting of adult patients

The Ministry hopes that daily visiting will become the general practice of hospitals which admit children, and it says, "it may even be that visits can be allowed more frequently than once a day"

AMŒBIASIS

A DISCUSSION by the Royal Society of Tropical Medicine and Hygiene, on Jan 19, made it clear that amœbiasis is important in Britain, partly because the infection is quite often found in people who have never been abroad, partly because it is a common and sometimes serious cause of ill health in those who have lived in the tropics, and partly because the many drugs advocated in recent years need careful and critical assessment

Dr A R D Adams, of Liverpool, speaking of intestinal amœbiasis only, declared that for the acute attack nothing has so far equalled emetine, that to eradicate the infection a three week intensive course of emetine bismuth iodide should be undertaken, that of the arsenicals acetarsol is probably the best, that retention enemas of 'Chiniofon' are sometimes useful, and that the antibiotics have not justified themselves for routine treatment, and should be reserved for exceptional cases and used with care

Prof A W Woodruff and his colleagues, Dr S Bell and Dr F D Schofield, described several hundred cases treated during several years on a careful plan to evaluate the various drugs used Like Dr Adams, Professor Woodruff was unequivocal that emetine bismuth iodide is at present the drug of choice in chronic intestinal amœbiasis (with emetine itself for the acute attack), and he cited a known relapse rate of 3% in his series—possibly a rather low estimate in view of the difficulties of prolonged observation, but nevertheless comparing favourably with other courses This team of workers also tested chloramphenicol (poor), aureomycin (poor), oxytetracycline (unsatisfactory), fumagillin (disappointing), 'Camoform' (unsatisfactory), 'Glaucarubin (not so good as emetine bismuth iodide, but useful and cheap), and a new drug 'Entamide' (fairly useful and cheap) Some of these drugs have considerable value, but they did not stand comparison with emetine bismuth iodide, nevertheless, lack of toxicity and cheapness are factors Prolonged use of the antibiotics may be risky

Sir George McRobert referred to the historic importance of the introduction of emetine for amœbiasis by Sir Leonard Rogers forty five years ago, but made the important point that emetine bismuth iodide is still too expensive for the Indian peasant There is danger in relying on antibiotics in cases of amœbic hepatitis, which responds to emetine or chloroquine Accurate diagnosis is supremely important, and there are distressing stories of prolonged treatment with all the latest drugs in patients who have never had the disease Sir Philip Manson-Bahr agreed that in India and Africa the diagnosis has been grossly overdone, and he too advocated treatment with emetine bismuth iodide, as he always has done Group Captain W P Stamm thought that the toxicity of emetine has been much over stressed, and like some other speakers he doubted the value of retention enemas Major General A Sachs, and other speakers, referred to the psychological effects of an attack of acute amœbiasis—itself a condition materially affecting the health and comfort of the patient

MOZART'S DEATH

FEW men have made such a generous contribution to music as Wolfgang Amadeus Mozart, who was born at Salzburg two hundred years ago, on Jan 27, 1756, and who composed and played instruments at the age of five and died, at the peak of his powers, only thirty years later Over 600 of his compositions have been published, including 20 masses, 23 operas 49 symphonies, and 27 piano concertos

There has been much speculation about the disease which killed Mozart at so early an age, and the many and conflicting reports have lately been discussed by Dr B Juhn[1] Five of Mozart's brothers and sisters died in infancy, apparently of inanition there was a belief in his family that children should be fed on water and not milk His father probably died of coronary thrombosis, and his mother's death was certified as *maladie du cœur* At a very early age Mozart began a nomadic life which was later spent in search of patronage and a living He was desperately poor, and was in the habit of working late at night, he was dogged by worries, fears, disappointments, hunger and illness He had scarlet fever in 1762, typhoid fever in 1765, smallpox in 1767, an undefined febrile illness the next year, and pneumonia in 1781 Because of Mozart s active life, Dr Juhn dismisses one suggestion that he had rheumatoid arthritis and endocarditis, and another that he had tuberculosis, it is true that at the age of six a physician found a nodular skin eruption on his shins, elbows, and buttocks which could have been erythema nodosum, but hæmolytic streptococci may have been responsible

Mozart began to ail in the late autumn of 1791 and he believed he had been poisoned Œdema of his hands and feet developed, and he complained that he could "taste death on his tongue"—a probable indication of excess urea and ammonia in the saliva Attacks of dyspnœa followed, with convulsions, delirium and severe headaches, and he died in coma on Dec 6, 1791

The cause of his death was certified as *Hitziges Frieselfieber* or "sweat rash," an epidemic and often fatal disease of those days, but Dr Juhn suggests that all the evidence points to malignant nephrosclerosis producing uræmia and heart-failure the nephrosclerosis could have been a result either of nephritis following scarlet fever, or of malignant hypertension Some people at the time, however, thought that he had typhus, and he was buried in Vienna, in a pauper's grave, the position of which is not known

---

Plans for new Hospital at Hong-Kong

The Hong Kong government have approved plans for a new hospital of 1275 beds to be built in Kowloon The estimated cost is £3¼ million, and when completed in 1960 it will be the biggest hospital of its kind in the Commonwealth

TABLE III—FREQUENCY OF SIGNS AND SYMPTOMS OF NAPHTHALENE POISONING IN TEN CASES

Case no	Systemic manifestations	Hæmatological manifestations	Urinary manifestations
10		Hæmolysis	Urine port wine coloured
9		Leucocytosis	
8	Pallor	Reticulocytosis	
7	Fever	Raised serum bilirubin level	Hæmoglobinuria
6	Jaundice gastro intestinal symptoms		Albuminuria, white cells
5	Palpable liver	Immature red cells in film	Granular casts
4	Palpable spleen		Red cells
3	Neurological symptoms	Raised serum urea level	General urinary symptoms, raised urobilinogen level
2			Naphthalene metabolites found
1		Heinz bodies, Howell Jolly bodies, sickle trait	Bilirubin, naphthalene odour

vitro *α* naphthol was the strongest hæmolytic agent, while naphthalene was not hæmolytic at all, injected intravenously into rabbits only *α* naphthol was hæmolytic Zuelzer and Apt (1949), however, produced hæmolysis with naphthalene in dogs and noted the following sequence of events (1) diarrhœa, leucocytosis, and Heinz bodies in erythrocytes, (2) apathy and hæmolysis, (3) reticulocytosis, and (4) recovery They also found slight hæmolytic activity in the serum of one of their patients

3 necropsies (Wiedow 1914, Konar et al 1939, Schafer 1951) did not reveal any lesions characteristic of naphthalene poisoning In 2 of these necropsies deposits of hæmoglobin were found in the kidneys, and naphthalene was found in the gastro intestinal contents, urine, and tissues

Discussion

In 1920 Smillie treated 81 cases of hookworm infestation with β-naphthol Only 4 of the patients showed signs of intoxication, and Smillie thought that their history of malaria was of ætiological importance The cases reported by Zuelzer and Apt (1949) were all in Negro children, of whom only 1 had sickle cell trait (although there was pronounced sickling during the acute phase) Ullmann (1947) emphasised the hæmolytic tendencies in the sector of the community his patient came from However, cases were reported from Germany and England and in white Americans It seems, therefore, that no known factor is responsible for increased sensitivity to naphthalene Zuelzer and Apt (1949) have assumed that the different responses to naphthalene depend on variations in intestinal absorption of naphthalene and/or the detoxifying efficiency of the liver No better explanation can yet be offered

Therapy consists mainly of replacement of hæmolysed red cells Whether cortisone acts unspecifically by combating stress or specifically influences the hæmolytic process is unknown

The prognosis rests on two factors—the extent of hæmolysis, and the degree of kidney damage Some workers report oliguria and transient anuria, Schafer (1951) found deposits of hæmoglobin in the kidney collecting tubules at necropsy. Blockage of the tubules by hæmoglobin cylinders and lower nephron nephrosis may cause death

As shown above, the number of leucocytes increases before hæmolysis takes place This early leucocytic response is caused apparently by gastro intestinal damage, symptoms of such damage being the very first an sometimes only signs of naphthalene intoxication I would be interesting to observe the hæmatologic response to parenteral naphthalene

The neurological symptoms are caused mainly b cerebral anoxia Typical in this respect was the euphor in our patient—similar to air pilots' euphoria at gre heights Convulsions, sometimes reported (Goetze 189 Zuelzer and Apt 1949), are possibly caused by blockag of cerebral capillaries by hæmoglobin

The early abdominal pain is undoubtedly due to gastr intestinal irritation Later pain has been reported in th regions of the gall bladder and the spleen This latte pain was complained of by our patient, but on palpatio the tenderness appeared to be in the region of the kidney The same may have been true of the other reported cas of pain in the spleen and gall bladder regions

The frequency of signs and symptoms in the recentl reported cases and ours is summarised in table III

The clinical picture of naphthalene poisoning emergin from the review of these cases is as follows

During the first 24 hours after ingestion only gastro intestinal symptoms of varying severity are noted, mainl nausea and vomiting

On the 2nd day fever and leucocytosis appear, which la several days

These are followed on the 3rd day by pallor, prostration, an rapid destruction of erythrocytes, accompanied by the usua signs of hæmolytic jaundice and hæmoglobinuria The urin assumes a characteristic port wine colour The spleen and live may be enlarged, and signs of kidney damage may appear albuminuria, hæmaturia, and granular casts in the urine Naphthol may be demonstrable in urine at this time

After 5–6 days, the leucocytes revert slowly to norma numbers, the hæmolytic process comes to an end, and there i a well marked reticulocytosis Oliguria or anuria, due to a lower nephron nephrosis or to blockage of renal tubules with hæmoglobin, may now supervene, or convalescence may begin, which, in absence of complications, is rapid

Summary

A case of suicidal naphthalene poisoning is reported, and published cases are reviewed

The clinical picture comprises gastro intestinal disturbances, fever, leucocytosis, hæmolysis and jaundice, signs of cerebral anoxia, hæmoglobinuria, renal damage, and eventual recovery

A plea is made for wider recognition of this syndrome

ADDENDUM

Since this paper was written another patient who had attempted suicide with 10 g of naphthalene was admitted to our department within 4 hours of taking the drug Treatment with 100 mg cortisone daily was started at once and no symptoms of intoxication developed, although 24 hours after admission naphthalene derivatives were found in the urine and Heinz bodies in blood films It remains to be demonstrated experimentally whether cortisone can prevent naphthalene induced hæmolysis or whether individual susceptibility varies greatly

INDUSTRIALISATION AND COMMUNITY LIVING *

A LESLIE BANKS

M A Camb , M D Lond , F R C P , D P H

PROFESSOR OF HUMAN ECOLOGY, UNIVERSITY OF CAMBRIDGE

IN medieval as in ancient times, children were taught to work with their hands from an early age—e g , from about 4 or 5 years—and the apprenticeship system meant that by the time a man had reached his teens he was already experienced in his craft, and a few years later was a master-craftsman The short duration of life at that time, and its uncertainty, were therefore compensated, to some extent, by this early start With the growth of mechanical power, and the rise of the industrial towns, the use of child labour was extended, and life became even more brief and uncertain , for many of these unfortunate little waifs never reached adult life because of the shocking conditions under which they worked Those who did remained the slaves of the machines, and had neither the opportunity, nor the satisfaction, of becoming craftsmen

Conditions in Britain today would appear Utopian to the workers of the early years of last century Hours of work are now less than half, wages are high, health and welfare services are secure, housing is reasonably good, and there are more facilities for the use of leisure Would the medieval craftsmen have been as envious ? I doubt it, for they would find something missing The swing of the pendulum has carried those who work in industry into large and impersonal undertakings , their homes are often in dormitory areas remote from the life of the city or town centre, and much of their leisure is spent passively, in watching, rather than creatively

No one would wish to return to the brief and hard life, the smells and squalor, of a medieval city , but the fact remains that the men of those times were able to take pride in producing, by their own skill, works of the highest quality and beauty , the spinsters really did spin, and life, though short, was truly communal Which all boils down to saying that they had certain incentives which are lacking today Or, if you prefer alternative definitions, they had motives, provocations, or spurs, that roused them to live their short lives fully What were those motives ? Firstly, as already noted, life was brief and uncertain, death came readily to the young as well as to the old, and "men feared death as children fear the dark" Secondly work was a natural thing As Francis Bacon said, in his *Advancement of Learning*, "But men must know, that in this theatre of men's life it is reserved only for God and angels to be lookers on" Thirdly, skill was an essential, and "He that hath not the craft let him shut up the shop" to quote an ancient proverb Most important, the standard of workmanship was judged by fellow-craftsmen, for "a workman is known by his work" Finally, the numbers of the people were relatively small, and life was lived in common, whether in town or village

It will be noted that I have omitted the greatest incentive of all, the spiritual , not because I do not believe in it, but because no amount of academic discussion will replace it if it has been lost

The Current Picture of Industrialisation

Before we attempt to compare those times, and incentives, more closely with our own it will be advisable to examine the magnitude of the problem with which we, in this country, are trying to grapple According to the 1955 edition of the *Official Handbook on Britain*, the United Kingdom is one of the most highly industrialised countries in the world[1] , for ten people work in mining manufacturing, and building, for every one in agriculture Of the total number of persons in civil employment in 1950 about 22½% were said to be employed by public enterprise and 77½% by private enterprise In manufacturing and building 96% of the persons engaged were employed by private enterprise "Also in terms of employment, only about 30% of the public utilities—gas, electricity, water and transport—was the concern of private enterprise"[2] An interesting mid century position in which to find ourselves

Over a quarter of all employees in manufacturing industries are in establishments employing from 100 to 500 persons , but there is a slow and significant trend towards an increase in size, for in May, 1952, establishments with 1000 or more employees were found to employ 2,224,000 persons—more than twice as many as in 1935 It should, however, be noted that a single firm or combine may own many different establishments

We have thus three main components as a result of industrialisation The employers and their associations (there are about 270 national federations and probably about 1600 other employers' organisations) , the State, which is also an employer , and the workers with their trade unions The State departments concerned include the Treasury, the Ministry of Labour and National Service, the Board of Trade the Admiralty, the Ministry of Supply, the Ministry of Agriculture, Fisheries, and Food, the Ministry of Fuel and Power, the Ministry of Transport and Civil Aviation, the Ministry of Works, the Ministry of Housing and Local Government, the Ministry of Health, and the Post Office—a formidable and impressive list

At the end of 1952 there were in Britain 690 separate trade unions with a total membership of 9,525,000, but 67% of all trade unionists were in 17 big unions The total working population of the United Kingdom in 1954 was just over 24 million—i e , some 47% of the total population About 95% of British men of working age (15 years to 64) were in or seeking gainful work The remainder were students, severely disabled persons, or of independent means The proportion of women of working age (15 years to 59) working or seeking gainful work was about 45% There were about one million older men and women still at work, in addition to those of normal working age Of these vast numbers only about 1¾ million were employers or self-employed The majority of the female labour force was under 35 years of age[3]

Nearly 45% of those in civil employment were engaged in the mining and manufacturing industries and only about 5% in agriculture and fishing Women in industry were chiefly employed in the manufacture of textiles, clothing, food, drink, and tobacco, and in the distributive trades and professional and miscellaneous services

Among the changes of this century has been an increase in those employed in administration, including 1,400,000 women clerical workers and typists (1951 census, one per cent Sample Tables), an increase in nurses (now nearly a quarter of a million) and women teachers (220,000) There has been a decline in employment in coal mining, cotton textiles, and agriculture, and in private domestic service On the other hand, employment in metals, engineering and vehicles, and the chemical groups of industries, has doubled in the past twenty years There has also been a considerable increase in the numbers employed in the distributive trades

It is clear, therefore, that with a labour force five times the total population of England in the time of Elizabeth I, and an annual import and export of goods measured in thousands of millions of pounds sterling (in 1953 total imports c i f were £3345 million and exports of United Kingdom goods f o b £2582 million), comparisons with the conditions of medieval times are several attacks of laryngeal spasm caused cyanosis, and it was feared that tracheotomy might become necessary, but laryngeal toilet and a little more thiopentone proved effective The nasal catheter undoubtedly increased secretion and eventually caused ulceration with a sanious discharge

---

* From a paper given to a conference of the Industrial Welfare Society on Oct 21, 1955

Nursing

The patient was nursed in a darkened room, making all procedures more difficult The patient was turned hourly, changed often, sucked out as required, and observed continuously so that, if necessary, the doctor could be summoned quickly

Progress

On the fourteenth day of anæsthesia the thiopentone was omitted from the intravenous fluid for a few hours, and not much increase in muscular tone was observed Next day 500 ml of blood was given to correct anæmia Intravenous therapy was discontinued on the sixteenth day Chloral was given for twenty four hours, during which the boy gradually regained consciousness, cried, and drank some water Convalescence was complicated by staphylococcal septicæmia, which responded slowly to antibiotics During this period he overheard a statement on a ward round that he had been in hospital for three weeks He resentfully insisted that he had only been in for a week He had of course no memory of his fortnight's anæsthesia The boy's temperature became normal four weeks after admission, and after some re education in walking, he was discharged

Follow up

When he was seen as an outpatient two weeks later it appeared that after a week's country holiday he had returned to the physiotherapy department demanding another week of exercises "so as to be good and strong for school" He is a bright boy

Discussion

Tracheotomy, with its dangers and difficulty of management, may be avoided if spasms are controlled with central depressants only In some cases even severe spasms can be controlled with central depressants without bad effects, and even more than 40 g of thiopentone may be harmless to a healthy child

The nutrition of a patient with tetanus must be maintained because his need for calories is increased, whether or not he has spasms (Holmdahl and Thoren 1954) His nutritional and electrolyte needs can be supplied by continuous intravenous and intragastric fluids An indwelling nasal catheter should be either used intermittently or changed often from one nostril to the other to avoid ulceration The staphylococcal septicæmia of our patient was possibly introduced by such ulcerations

This case shows that neither a short incubation period, nor a short interval between the first symptom and the first generalised reflex spasm, is a bar to a successful outcome in tetanus

Summary

A case of tetanus with an apparent incubation period of thirty-six hours is reported with recovery after two weeks' anæsthesia maintained with thiopentone

Relaxants were only used for short periods on two occasions for the passage of nasal catheters

My thanks are due to Mr F G Badger, under whose care this patient was, for guidance in the management of the case and in the preparation of this paper, Dr L J Wolfson, Dr D Bigley, and Dr R E Graham for advice on anæsthesia, Dr Mary Fisher for long periods of observation, and the nurses for their watchful care of the boy

CHIARI'S DISEASE

A CASE DIAGNOSED DURING LIFE

T St M Norris
M D Camb, M R C.P, D P.H.
PHYSICIAN, WHITTINGTON HOSPITAL, LONDON

PRIMARY thrombosis in the hepatic veins has been recorded comparatively rarely since Chiari's (1899) account of 1 man and 2 women who died from this disorder Chiari suggested that the thrombosis was the result of endophlebitis

Armstrong and Carnes (1944) said that about 60 cases of the disease had been described, and that at Stanford University only 5 had been found in 11,979 necropsies—a prevalence of 0 042%

Kelsey and Comfort (1945) found 20 cases in all necropsies at the Mayo Clinic between 1910 and 1939 In only 4 of these was thrombosis of the hepatic veins the major factor, in the remaining 16 it was secondary to some other condition.

Little and Montgomery (1952), who reported 115 cases found that the most common causes were intra abdominal malignant disease, inflammatory conditions, and blood dyscrasias

Thus the disease in many of the cases reported since Chiari's first description was probably secondary to some other illness or was a terminal event

1 patient with the primary condition was first seen with hepatomegaly at the age of 5 and was kept under observation until his death at the age of 28 (Hutchison and Simpson 1930), at necropsy, primary carcinoma of the liver superimposed on obstruction of the hepatic veins was found

Most cases have not been diagnosed until necropsy, an exception was a patient who was admitted to a surgical ward with pyrexia, recurrent jaundice, and hepatosplenomegaly (Baer and Klemperer 1930) Thrombosis of the hepatic veins was considered the probable diagnosis, but cholangitis was not excluded, the former diagnosis was confirmed at necropsy Baer and Klemperer added that portal-vein thrombosis is difficult to diagnose, but the symptoms of hepatic vein thrombosis are more characteristic, comprising right sided upper-abdominal pain radiating to the back, a large, tender liver, splenomegaly, and ascites

Case-report

A male printing machine operator, aged 30, attended the outpatient department on Dec 17, 1952, with a history of abdominal distension and diarrhœa for three weeks, and lower thoracic backache for two weeks From 1941 to 1945 he had served in the R A F as a wireless operator/air gunner but had not lived abroad During and after his service career he had had attacks of epigastric discomfort which were not investigated

On examination he looked ill There was massive ascites which prevented palpation of the abdominal viscera and pressed on the bases of the lungs There was no evidence of heart-disease, the blood pressure was 145/95 mm Hg

Investigations

The patient was admitted the following day and a sample of the ascitic fluid was withdrawn This was faintly bile stained, and it contained 2 4 g per 100 ml of protein and was sterile on culture Chest radiography was normal Hæmoglobin was 97%, and the leucocyte count and blood films were normal, the total serum protein level was 6 g per 100 ml (albumin 3 4 and globulin 2 6 g per 100 ml) the results of this and subsequent estimations are shown in fig 1 Thymol turbidity 5 units, alkaline phosphatase 6 units, and serum bilirubin level 0 2 mg per 100 ml The Wassermann and Kahn reactions were negative

The similarity between this case and the clinical history attached to a specimen of liver (Pearson 1939) in the hospital pathological museum led me to diagnose Chiari's disease

Further Investigations and Progress

The patient remained in hospital for six months, during which abdominal paracentesis was necessary every five to eight days, when 10–14 pints of fluid was withdrawn After the first paracentesis the liver but not the spleen was palpable

On Jan 2, 1953, liver biopsy, by needle puncture, revealed the centrilobular congestion and dilated blood spaces on a national scale are costly. In short it is designed for braking rather than for acceleration.

Much the same comments apply to regional control. For advisory and planning purposes, for distributing the load evenly and strengthening weak places, a regional organisation is excellent. But the men who sit on regional boards can, in the nature of things, know little about conditions in detail in their regions, and nothing whatsoever about the needs of individuals other than those with whom they may come into contact. Are conditions any better under private enterprise? I do not know, but I suspect that the larger the enterprise the less the individual employed in it feels a sense of personal responsibility, and we are unquestionably moving into an era of large enterprises.

I have also found that the most severe judges of a workman are his fellow men, and the iron discipline of some trade unions can be just as harmful as a harsh employer or a remote and impersonal board—indeed more so, for the latter can only operate within certain limits, whereas the former may influence the whole life of a man.

With the vast numbers now employed in industry and the complex machinery of organisation, it is possible, without drawing too much on the imagination, to foresee the possibility of a future in which the individual has no place other than as a unit, to be paid a standard wage (without regard for *good* or *bad* work), for standard hours, provided that he obeys the rules drawn up by the State, the employing body, and his fellow workers. In such a community the penalties for making a wrong decision might greatly exceed the rewards for showing initiative and making the right one, and the punishment for ineptitude might be transferred from the act of being guilty of it to the "crime" of being found out.

It is clear that the requirements of any industrialised country in the future will call for a high level of intelligence in its workers. Unskilled and manual workers will be increasingly replaced by mechanicians and technicians sufficiently familiar with control panels, and laboratory techniques, to take charge of automatic and semi-automatic processes and to be able to detect and remedy causes of breakdown. In such a society it is equally possible to foresee at least a partial return to pride of craftsmanship, particularly if this is fostered by careful preliminary training and regular "post-graduate" instruction, so that the individual is made to feel that he is a part of the whole—"a piece of the main" to quote John Donne. To ensure this will require, in my opinion, more attention to the instruction and advice given to those about to enter industry, and this, in turn, calls for combined action by employers, trade unions, Government departments, and education authorities.

It is also possible that, with increasing ease of control, the hours required to be worked will be shorter, quite apart from the efforts of organised labour in this direction, and the problem of the proper use of leisure, already a considerable one, will loom large. At present we think in terms of a shorter day, or a five-day week, and leave the individual to fill in his spare time as best he can, with the result that, in many instances, he becomes a passive watcher of screens and games, a process which can distil off his earnings without much benefit to himself. Is it too far-fetched to think instead of longer hours of work and longer vacations? If my arithmetic is right, it would be possible to replace a forty-hour week with a fortnight's holiday each year, by a sixty-hour week with three months' holiday, and have some additional 340 hours of work in hand for each individual at the end of the year. It might be asked what would a man do with a longer holiday. My experience of university folk is that they use their vacations to do all the interesting things they cannot do in term-time—such as composing fantasies like this.

I do not suggest that everyone should have three months' holiday each year, but rather that we should get away from the concept of shorter days and shorter weeks, in favour of longer periods of leisure at longer intervals. University teachers can accumulate sabbatical leave term by term, until it amounts to a sabbatical year, which they can then spend in study away from their university. They are not compelled to take it, but the principle is a sound one, and I see no reason why it should not be extended to industry, so that a conscientious worker could accumulate sufficient leave to enable him to do something worth while with it. Some of the arguments against the scheme are obvious: men will then do two jobs, it will cause inconvenience if everyone is away at once, it will interrupt the smooth flow of production, &c., &c., but I do not think that these upset the principle.

I have put forward this proposal on the assumption that the worker of the future will be an intelligent and responsible being, who will prefer to work hard when he is working in order that he may have enough leisure to do interesting things. At the moment the yardstick of prosperity is a material one, as represented by articles which can be bought on a hire-purchase system. If Utopia is to consist of bigger television sets, deep-freeze refrigerators, and more cars on the road, then I am wrong. If it is to comprise opportunities to see and study something of the rest of the world and to live a full life then I am right. Benjamin Franklin who had many sayings about the value of time, wrote truly when he said "Dost thou love life? Then do not squander time, for that's the stuff life is made of". There is more in life than forever fighting for a fatter weekly pay-packet, and then squandering it.

Industrialisation and community living can be made practicable in the future if, (*a*) the worker in industry can be made to feel that he is an essential and integral part of the organisation on which his life, and that of his fellows, depends, (*b*) he is prepared to work for his leisure, and (*c*) that leisure is properly used. There are so many nice things to do, and life slips by so fast. There is more to it than was imagined by Æsop's fly when it sat upon the axle-tree of the chariot wheels, and said, "What a dust do I raise!"

4. Quoted by Prof. Clyde Dankert in the *Contemporary Review*, September, 1955, p. 159.

"The emergence of middle-aged men as a 'vulnerable group' is the most startling occurrence for a public health movement whose ideas on prevention are based largely on such experiences as maternity and child-welfare work. The nineteenth century epidemics, bred in poverty and malnutrition, arose from failures of the social system. But coronary thrombosis (and there is no reason to suppose it is unique), with its origins apparently in high living standards and our means of achieving these, seems to be arising from what we regard as successes of the social system, and from the essential processes of our new industrial society. There is every reason to expect that, as social progress continues along its present lines, we shall have not less coronary thrombosis in the future but more. Over and above that, it is becoming clear that in the modification of personal behaviour, of diet, smoking, physical exercise, and the rest, which look like providing at any rate part of the answer, the responsibility of the individual for his own health will be far greater than formerly. It will not be possible to impose from without (as drains were built) the new norms of behaviour better serving the needs of middle and old age. They will come about only in a new kind of partnership between community and individual. And if it turns out that the 'wisdom of the body and understanding of the heart' begin with a rather dull *moderation in all things*, perhaps even that is not a negligible message from preventive medicine to these over-excited times."—Dr. J. N. Morris, *Listener*, Dec. 8, 1955, p. 997.

Histological Examination

Extensive destruction of liver parenchyma left only islands and cords of liver cells round some of the portal systems, and nodules of regeneration The rest of the liver consisted of a coarse network of œdematous fibrous tissue containing many dilated blood spaces and veins, some showing proliferation of the intima, others fibrous obliteration and recanalisation Sections through the closed ostia of the hepatic veins showed hypertrophy and fibrosis of the muscularis and œdematous hyaline fibrous tissue with many small channels of recanalisation, replacing the intima and obliterating the lumen

Discussion

This case and that of Pearson are classical examples of Chiari's disease The clinical picture varies with the degree of obstruction of the hepatic vein In total obstruction the illness is short with the rapid development of hepatomegaly, ascites, vomiting, and jaundice, death from hæmatemesis due to ruptured œsophageal varices usually follows When the obstruction is incomplete hepatomegaly and ascites may develop rapidly, but the patient may live for several years, improvement depending on the formation of a collateral circulation and regeneration of the liver The early onset of ascites supports the view of Madden et al (1954) that an important factor causing hepatic ascites is imbalance between the hepatic inflow and outflow of blood

If the disease is suspected diagnosis should not be difficult, because the picture is that of acute hepatic congestion unassociated with hypertension in the superior vena cava, if the patient lives long enough, secondary portal hypertension develops Differentiation from constrictive pericarditis and tricuspid regurgitation rests on the clinical history, the absence of raised jugular pressure, and the absence of the hepato-jugular reflex

Treatment is unsatisfactory, anticoagulants are dangerous because of hepatic damage, and surgery is of doubtful benefit Symptomatic treatment and prolonged rest seem to offer the best prospects of improvement

A clear distinction should be made between cases of primary obstruction, as described by Chiari, and those in which obstruction of the hepatic vein is secondary to another disease

I am grateful to the staff of the Archway Group Laboratory for their assistance in the clinical pathology, especially Dr J G A McSorley and Miss M F Crowley

SPONTANEOUS HYPOPARATHYROIDISM WITH MEGALOBLASTIC ANÆMIA

L J HURWITZ
B Sc M D Belf, M R C P E
FORMERLY REGISTRAR, DEPARTMENT OF NEUROLOGY, CLAREMONT STREET HOSPITAL, AND ROYAL VICTORIA HOSPITAL, BELFAST

THE following case of idiopathic hypoparathyroidism is reported because of its association with megaloblastic anæmia—an association not previously reported

Case-report

A girl, aged 19, began to have fits at the age of 8 years There was a constant aura consisting in a feeling of stiffness in the right hand lasting some moments Usually this was followed by generalised convulsions The fits might be as many as 12 in a day, but sometimes the patient went 3–10 months without any At the age of 11 years she began to take phenobarbitone gr $^1/_2$ b d and phenytoin sodium gr $1^1/_2$ daily In March, 1953, the latter was increased to gr $1^1/_2$ b.d., but the fits continued, and in April, 1954, the patient was admitted to Claremont Street Hospital, Belfast She had no history of infantile convulsions or of head injury, and she walked and talked at the normal age Menstruation had not begun She was the eighth child in a family of nine There was no history of epilepsy or other neurological illness in the family

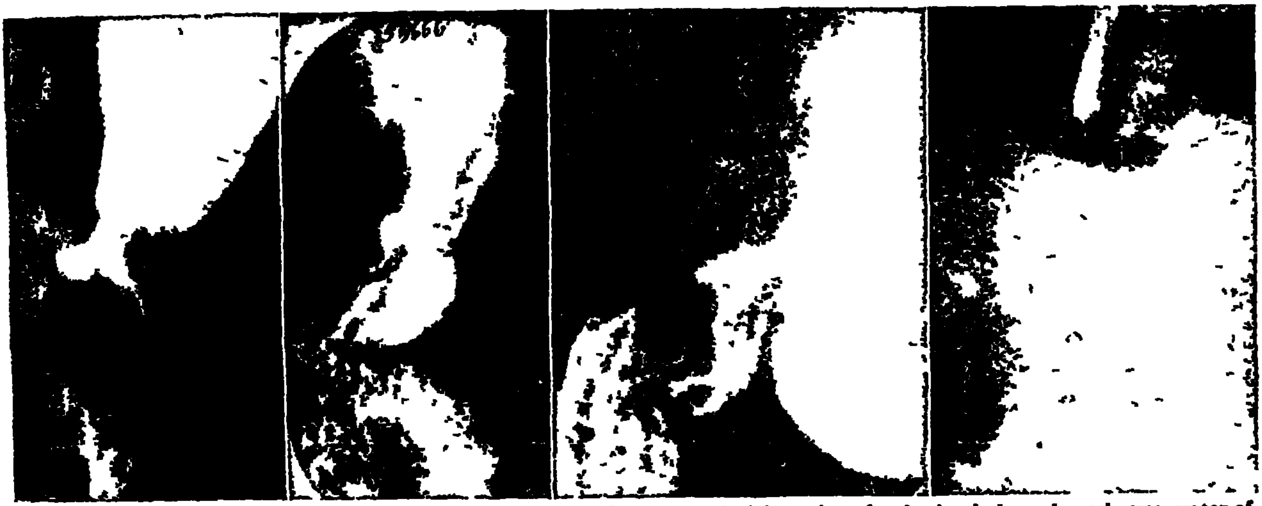
On examination on April 28, 1954, she was cheerful, of average intelligence, small, and plump, with a round face and squat build Height 58 inches, heel to pubis 29 inches, from finger tips to finger tips of outstretched arms 61 inches skull circumference $20^1/_2$ inches Scanty pubic and axillary hair, breasts poorly developed, skin dry, nails apparently normal, but teeth much deformed and widely separated, several being just small stumps There was a butterfly area of brownish pigmentation on the face Chvostek sign easily elicited, Trousseau sign positive Blood pressure 100/60 mm Hg Heart sounds normal, mucosæ pale. Neurological examination negative Lens opacities in both eyes

Investigations—Radiography showed calcification of skull in region of basal ganglia, metacarpals and metatarsals normal, bone age 12 years, no subcutaneous calcification, long bones normal, no abnormal calcification in abdomen. A fractional test meal showed histamine fast achlorhydria Examination of the blood showed Wassermann reaction negative, hæmoglobin 55% (7 9 g per 100 ml), colour index 1 37, packed cell volume 24%, mean corpuscular volume 120 c µ, mean corpuscular Hb concentration 33 g per 100 ml erythrocyte sedimentation rate 57 mm in 1st hr (Westergren), leucocytes 3350 per c mm (neutrophils 48%, lymphocytes 48%, eosinophils 4%), reticulocytes less than 0 5% A blood film showed macrocytosis and poikilocytosis Plasma bilirubin 0 7 mg per 100 ml, plasma protein 9 0 g per 100 ml (albumin 5 8 g, globulin 3 2 g per 100 ml), serum calcium 5 4 mg per 100 ml, serum phosphorus 11 8 mg per 100 ml, alkaline phosphatase 16 King Armstrong units The Ellsworth Howard test showed poor response to intravenous 'Para thor mone' A glucose tolerance test produced a flat curve An insulin sensitivity test was normal A fat balance test (on two occasions) showed 90% and 95% reabsorption Radiography after a barium meal showed a normal intestinal pattern A Sulkowich test showed no calcium in the urine The basal metabolic rate was +17% Intravenous pyelography showed both kidneys normal in size and very good concentration of the contrast medium Blood urea 23 mg per 100 ml The specific gravity of the urine was 1 000–1 020, and a urea concentration test gave 2 6% The Kepler test was negative The urinary excretion of 17 ketosteroids was 2 5 mg in twenty-four hours

Lumbar puncture produced clear cerebrospinal fluid containing protein 35 mg per 100 ml, and leucocytes 1 per c mm, the Wassermann reaction was negative Electrocardiography showed a slight increase in the Q–Tc interval Electro encephalography on May 8, 1954, gave a resting record which showed activity at a wide range of frequencies $1^1/_2$–9 c p.s With hyperpnœa the slow activity was clearly dominant Chromatography showed increased amino aciduria of a general pattern

Prof P J Stoy reported that radiography on June 23, 1953, showed the following teeth erupted $\frac{654321/123456}{7\ 5432\ /\ 2345\ 7}$ The following teeth were present but unerupted $\frac{7/7}{8\ /\ 8}$ The teeth were widely spaced except 7/7, which were erupting, the $\underline{7/}$ being mesio angularly impacted against the $\underline{6/}$ The $\underline{/7}$ was in normal position The roots of all the teeth were incompletely formed and stumpy The lamina dura was prominent and the periodontal shadow broad The dental age of each tooth was as follows (Symington and Rankin being taken as a guide)

$\underline{1/1}$	8 years	$\overline{2/2}$	8 years
$\underline{2/2}$	8 years	$\overline{3/3}$	8 years
$\underline{4/4}$	8 years	$\overline{4/4}$	8 years
$\underline{5/5}$	8 years	$\overline{5/5}$	8 years
$\underline{6/6}$	7–8 years	$\overline{7/7}$	9 years
$\underline{7/7}$	9 years		



Radiographs after barium meal in 4 cases in which Billroth-I gastric resection had been done for duodenal ulcer. In each case crater of large recurrent ulcer is on lesser curve of re-formed stomach just proximal to gastroduodenal anastomosis.

and site of recurrent ulceration, the frequency of post gastrectomy symptoms not due to ulceration (the so called post gastrectomy syndromes), and the functional state of the patient, determined by his fitness for work and his enjoyment of life. To assess these results and make as impartial a comparison as possible between the two operations, each patient was interviewed by a panel of three. To guard still further against bias, the panel usually made its preliminary assessment before consulting the patient's notes, so that its conclusions were often reached in ignorance of the type of operation that had been performed.

RECURRENT ULCERATION

Table III shows the number of patients with recurrent ulcers after the two operations. Proven ulcers were those found at a further operation, or demonstrated unequivocally by radiography or gastroscopy.

TABLE IV—RECURRENT ULCERATION IN PATIENTS FOLLOWED UP FOR AT LEAST THREE YEARS

Type of operation	No of patients	Recurrences		
		Proven	Suspected	Total
Billroth I	80	11	3	14 (*17·5%*)
Polya	106	1	1	2 (*1·9%*)

The difference between the two series is striking: the recurrence rate was 15·1% after the Billroth I resection, and only 1·5% after the Polya resection. These figures do not represent the final picture, because some of the patients treated more recently by these operations may yet have recurrences. However, most of the recurrences appeared within eighteen months to two years of operation, and a slightly more accurate estimate of the risks of recurrent ulceration may be reached by considering only the patients operated on at least three years before the survey (table IV). This also eliminates one of the main points of dissimilarity between the two groups—the duration of the follow up.

These figures confirm the much greater tendency to recurrence after the Billroth I resection. With this operation the recurrence rate after three years was 17·5%, whereas with the Polya operation the recurrence rate was only 1·9%.

Most of the recurrences were in men (who made up the bulk of the series), but 4 were in women, all of whom had been treated by the Billroth I operation.

Sites of Recurrences

After the Polya gastrectomy for duodenal ulcer, recurrence takes place in the jejunal mucosa close to the stoma. By analogy, any recurrences after Billroth I resection would be expected to lie in the exposed duodenal mucosa adjacent to the anastomosis. In the present series some of the recurrences were in the duodenum (table V), but it was surprising to find that the majority were on the lesser curve of the stomach. Findings at the second operation left no doubt that in 3 or 4 cases there were true gastric recurrences. In the other cases, however, the subsequent operations (sometimes a simple vagotomy without opening the stomach, sometimes a Polya conversion with little attention to the exact site of the ulcer) failed to establish the side of the anastomosis on which the ulcer lay, and the radiological diagnosis was accepted. But we were very doubtful about the location of many of these ulcers and wondered whether they were not stomal rather than gastric in position. The radiological diagnosis of ulceration in the region of the lesser curve is difficult because of the niche like appearances often found in this situation after a Billroth-I gastrectomy. Puckering and distortion are produced by the suturing of the upper part of the gastric remnant, which of course constitutes the lesser curve of the re formed stomach. We have therefore been cautious in interpreting radiographs and have restricted definite diagnoses to cases with obvious craters, as in the accompanying figure.

Incidentally, these radiographs give a good indication of the level at which we normally performed our Billroth-I resections. There was no question of the gastrectomy being skimped because a gastroduodenal anastomosis had to be considered.

It is difficult to explain the predilection for recurrent ulceration on the lesser curve after Billroth-I resection for duodenal ulcer, because no such tendency is apparent following this operation for gastric ulcer. In the past six years one of us (J C G) has treated a series of 124 patients with gastric ulcer by Billroth-I resection without

TABLE V—SITES OF RECURRENT ULCERS

Site of recurrence	No of recurrences	
	After Billroth I resection (132 patients)	After Polya resection (138 patients)
Duodenal or jejunal	6	1
On stoma	1	0
On lesser curve of stomach	11	0
Not clearly established	2	1

Reviews of Books

The Treatment of Renal Failure

Therapeutic Principles in the Management of Acute and Chronic Uræmia JOHN P MERRILL, M D, *associate in medicine, Harvard Medical School* New York & London Grune & Stratton 1955 Pp 238 48*s*

IN the past ten years, the underlying pathology of renal failure has been greatly clarified by Jean Oliver's microdissection studies, the conservative regimen of Borst and Bull has justified itself by results, and these patients are no longer filled with fluid (except perhaps in clinical backwaters), and the artificial kidney of Kolff has been modified and tested, and the related procedures of peritoneal and intestinal lavage have been given a trial In short, it was time for a critical review of the treatment of renal failure, based on adequate clinical experience Dr Merrill's book does this admirably

He has treated over 200 patients with acute renal failure, and he has also assessed the value of similar methods in alleviating the discomforts of chronic renal failure This experience enables him to give a balanced and richly documented account of what can be done Yet he is not dazzled, for he reminds us that in the cure, as opposed to the palliation, of renal disease, we are no better off than Richard Bright in 1836, and one of his sections on chronic renal failure is headed *When not to treat* There are some faults for example, it seems questionable to condemn hydrogen resins and allow ammonium resins, which contribute both urea and hydrion to the body

Nevertheless, this is the only book available which is not dedicated to the propagation of one method, but provides an adequately based survey of the different possible forms of treatment. Its merits should make it *the* monograph on renal failure for some years to come

Modern Apparatus for Sterilisation

J H BOWIE, M B, M R C P E London Pharmaceutical Press 1955 Pp 21 2*s* 6*d*

NOT many hospital administrators, or engineers for that matter, have the knowledge to differentiate good and bad dressing-sterilisers But eyebrows will be raised at the first sentence of this admirable little booklet, which reads "About 90 per cent of the sterilisers in use in Britain's hospitals and pharmacies are obsolete" One might suppose that the sterilisers thus decried were bought as the result of efficient sales talk rather than from a knowledge of the physics of steam sterilisation, and the section of the booklet on this subject turns supposition to certainty, for much of the information it gives will come as a surprise even to hospital pharmacists and pathologists whose familiarity with the basic sciences is probably closer than that of anyone else on a hospital's staff In the section on faulty design, it is alarming to discover that the apple of the theatre sister's eye—"the very latest pattern autoclave"—is indeed rotten at the core Although it may only lack a thermometer—as in 55 of the autoclaves which Dr Bowie inspected—and although it may not be acting as a short circuit between the underground drains and the main water-supply of the hospital, as happened with 2 sterilisers

Everyone connected, however remotely, with sterilisation by steam should study this reprint of an address given to the Pharmaceutical Society of Great Britain

The Postural Complex

Observations as to Cause, Diagnosis and Treatment LAURENCE JONES, B S, M D, *visiting orthopodist, Midway Hospital, Los Angeles* Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1955 Pp 156 70*s*

LOW back pain is a heavy burden on every orthopædic department in this country It became even heavier with the recognition that "lumbago" and sciatica were commonly, and some said universally, due to lesions of the intervertebral discs Operations on the discs are not as popular as they were and other diagnoses are coming into their own again, but the results of treatment are still far from satisfactory and many patients are still left with considerable disability Every new idea must therefore be examined and tested without prejudice

It is Dr Jones's theme that most cases of backache and neuralgias in the trunk and limbs (upper as well as lower) have their origin in the feet

The foot cannot roll inwards or outwards without rotation of the leg, if the leg rotates, tension in the iliopsoas alters, the pelvis therefore rotates forwards or backwards, and this, with the resultant changes in spinal curvature, produces alterations in tension in the nerves and spinal cord from one end to the other and consequent "neuralgias" in almost any situation There may be no symptoms whatever in the feet, but Dr Jones maintains that correction of even minor degrees of foot imbalance will cure the pain elsewhere, unless they are of such long standing that "secondary inflammatory changes" have already occurred For such changes, Dr Jones uses more standard methods, but maintenance of improvement depends on foot correction

In preliminary chapters on the morphology of the foot, he emphasises that the foot is becoming an increasingly rigid structure, on which basis he defends his use of "fixed rigid postural shoe corrections" The method he uses for stiffening the shoe before the fitting of the supports, &c, required by that particular patient involves the use of a 'Fiberglas' insert, and considerable apparatus is required to handle this material He is also at great pains to correct any inequality of leg length, which he says is substantial in 40% of subjects

The rationale of this hypothesis and these methods is argued at length in this book That foot deformities can produce rotation of the whole leg and a change in the degree of pelvic tilt is clearly demonstrated, but there is little objective evidence that this produces significant alteration in tension in the spinal cord Nevertheless, Dr Jones writes with enthusiasm and faith, he quotes large numbers of cases, and he is prepared to meet the scepticism which he rightly foresees While it is difficult to believe that this postural complex is either so general or so noxious as he believes, his book will make people think

Radio-Anatomie générale de la tête

ROBERT AUBANIAC, *agrégé d'anatomie*, JACQUES POROT, *assistant d'électro radiologie des Hôpitaux de Paris* Paris Masson 1955 Pp 152

WITHOUT a knowledge of anatomy it would be impossible to interpret radiographs, on the other hand, radiography has often been of value in helping to determine the anatomy of a particular part of the body This book is primarily an illustrated anatomical and radiological atlas of sections of the head in the three principal planes

The structures seen in sections of the head (16 in the coronal plane, 16 in the horizontal plane, and 5 in the sagittal plane) are described with the help of natural size annotated diagrams accompanied by an illustration of a radiograph of each section The description of each section includes comments on the features revealed by the radiograph Radiography has been used to increase the information obtained from the sections, since the radiographs reveal details in the thickness of the section which otherwise could not readily be seen

The text and index are supplied unbound, and the diagrams and radiographs, all well printed on good paper, are supplied as loose sheets in a thin card folder This arrangement has the disadvantage that the loose sheets may easily be lost or damaged, but it has the great advantage that for serious study diagrams of different sections may be removed and compared side by side The cardboard case is rather flimsy and could perhaps be replaced by a proper loose leaf binding

---

Textbook of Surgery (2nd ed London Kimpton 1955 Pp 1135 £6)—Only three years have elapsed since the publication of the first edition of this work by Mr H F Moseley, assistant professor of surgery at McGill University, but that is hardly surprising for it is an exceptionally good textbook It is up to date, clear, and comprehensive, and it has achieved wonders in catering for final year and fellowship students at the same time The new edition is enlarged by chapters on radioactive isotopes and on the acute abdomen, and there are now pictures in what was already a well illustrated book An original feature is the addition of film references to the orthodox bibliography

CONTROL OF WATER AND ELECTROLYTE DISORDERS

A SIMPLE CHART

J R K PREEDY
M.A., M.B Camb, M.R C.P
RESEARCH FELLOW IN MEDICINE

J E RICHARDSON
M S Lond, F R C S
ASSISTANT SURGEON

From the Medical and Surgical Units, London Hospital

THE application of modern knowledge of water and electrolyte disturbance is apt to raise difficulties in routine hospital practice, elaborate procedures making impracticable demands on nursing and laboratory staff On the other hand, it is of the utmost importance in both surgical and medical cases to prevent and to correct water and electrolyte disorders Therefore it is essential to devise a system whereby such disorders can be effectively controlled with the least expenditure of time by the hospital staff

Any instructions intended to cover all aspects of imbalance in full detail would clearly be unworkable, particularly as regards the maintenance of record charts House-officers do not have time either to understand or to maintain complicated charts and the primary object would then be defeated

Nevertheless a chart is essential for the following reasons (1) it makes treatment far easier to apply and more effective, (2) progress can be accurately followed and under-treatment or over treatment avoided, (3) impending disorders are more easily recognised and prevented and (4) more accurate control reduces the number of laboratory analyses

A routine chart for recording water and electrolyte balance should be as simple as possible, but at the same time the dangers of over-simplification of an admittedly complex subject must be avoided After prolonged trial and modification such a record chart has been evolved, and instructions, based on the chart, for the control of water and electrolyte disturbance have now been in routine use at the London Hospital for two years The instructions and chart we describe here

Record Chart

The chart is intended to be written up by house-officers from data obtained from the fluid-chart kept by the nurses, and from laboratory analyses (In the nurses' fluid-chart, intake of fluid is recorded as it is given Output of fluid is entered specimen by specimen under the headings of urine, suction, vomit, drainage, and diarrhœa)

The chart is designed for period-by-period comparison of intake and output of water and "electrolyte fluid" (see below) with urine and blood analyses Loss of "electrolyte fluid" can be directly compared, volume by volume, with replacement of electrolyte fluid, thereby rendering control more accurate and reducing demands on the laboratory. Three periods can be logged on each page, which is of the same size as the hospital case-notes, with which the chart is eventually filed

The back of the chart likewise provides for the logging of three periods Solutions prescribed for each period are entered, bottle by bottle, on the back of the chart, each entry being initialed by the nurse giving the fluid Thus there is a clear record of solutions actually given during a period, and this record can be directly compared with data for the same period on the front of the chart It is convenient to keep these orders for fluid together and apart from medicines, injections, and other items entered on the usual hospital treatment-form Space is provided for dietetic instructions for use where intravenous therapy is not indicated or no longer required

The format of the record chart is given in the accompanying table

The results of analysis of blood and urine must be rapidly available, so that accurate control may be maintained It has been found quite practicable to report the results within two hours of the arrival of the specimens in the laboratory, and this is the regular practice at this hospital Normal values for blood analyses are given on the back of the laboratory report

The following instructions are issued with the chart

The Management of Water and Electrolyte Depletions

USING THE RECORD CHART

(For House-officers)

Although the chart can be used equally well in pædiatrics, the following instructions apply mainly to adults.

ust the right combination...

Cold, damp and smoke — just the right combination to produce the fog which sets people coughing and sends them to their doctor in search of relief

And relief is readily available with 'Phensedyl', the **M&B** brand cough linctus which contains promethazine for its prolonged antihistamine, local analgesic and central sedative action, ephedrine for its broncho-dilator activity and codeine for its depressant effect on the cough reflex

Whatever the cause of cough — whether it is "smog", smoking, the aftermath of influenza, or a more serious condition — these properties of 'Phensedyl' usually bring relief They provide the right combination

Supplied in bottles of 4 and 40 fl oz
(each fluid drachm [3 6 c c] contains

PROMETHAZINE HYDROCHLORIDE	3 6 mgm
CODEINE PHOSPHATE	9 0 mgm.
EPHEDRINE HYDROCHLORIDE	7 2 mgm.)

'PHENSEDYL'

fluid loss is small (as in increased sweating or occasional vomits). It also supplies 100 g. of glucose (400 calories).

(C) Acid-base disturbances often occur in electrolyte depletion. These are usually rectified by the kidney if renal function is adequate, provided correct amounts of Na, Cl, K, and water are given. In severe acidosis or where large infusions of normal saline are required, isotonic Na lactate solution should take the place of a proportion of the normal saline solution. Often an alkalosis associated with K depletion can only be rectified by correcting the K depletion.

(D) Kidney function is often temporarily impaired in electrolyte depletions and after major operations. In these circumstances renal adjustment may be slow or imperfect. This can usually be detected by consecutive urine and blood analyses. Intravenous therapy should be applied with caution in these cases until kidney function recovers.

(E) Intravenous administration of K salts, although frequently essential, is potentially dangerous and should always be cautious. It is suggested that 1 litre of the intravenous KCl solution should be given slowly not more often than once in 6 hours. It may take up to 3 days or more to rectify K depletions completely, particularly if loss continues. K salts can be given by mouth, provided total water intake is increased proportionately (e.g., total intake 2·5–3·0 litres a day). Latent K depletion is often revealed only after a concurrent Na depletion has been rectified. Na depletions must, however, be rectified first.

(F) It is essential not to mistake the oliguria of a primary renal condition (such as acute anuria or acute nephritis) for a simple water or electrolyte depletion. The distinction should be clear from the clinical picture.

(G) In electrolyte depletion via the urine the extent of the electrolyte loss will be evident from blood and urine analyses. The necessary volume and composition of replacement fluid must be estimated from these. Here volume for volume replacement is clearly not applicable.

(H) With a new case complete urine and blood analyses should be made at the start. Subsequently less frequent analyses are required and not all the items on the record chart need be requested. Under "blood analysis" space is available for inserting additional estimations as required—e.g., hæmatocrit, plasma-protein level, &c.

(I) 5% and 10% dextrose solutions are charted under "water intake." It is convenient to chart the maintenance solution (note B) also under "water intake." Normal saline and Na lactate solutions are charted under "electrolyte fluid replacement." KCl solutions are not entered on the front of the chart, but the amounts given will appear among the initialed orders on the back of the chart in the corresponding period.

(J) A normal urinary volume is frequently not attainable in surgical cases on the first postoperative day.

(K) In almost all cases of severe electrolyte depletion intravenous therapy is required to begin with.

(L) In chronic electrolyte depletions—e.g., some cases of pyloric stenosis, diabetic coma, and Addison's disease—the depletions should always be corrected with caution. Cautious treatment allows time for body mechanisms to readjust to more normal conditions. Rapid intravenous infusions, for instance, are dangerous because pulmonary œdema may be precipitated.

Discussion

These instructions on management of water and electrolyte disorders are not meant to be in any way comprehensive but are notes put forward to enable the most efficient use to be made of the chart.

An attempt has been made to keep the number of intravenous solutions at a minimum and the composition of each solution as simple as possible. We feel that there is little indication for the use of more complex solutions. Complex solutions of fixed composition cannot meet the varying requirements of all cases and probably seldom meet fully the requirements of even one case. They may, indeed, give a false sense of security. In particular, the use of solutions containing phosphate has been avoided. Although there may sometimes be an indication for such solutions on theoretical grounds, in practice there are no known clinical features associated with a phosphate deficit alone.

There appears to be a need for an intravenous solution with a disposable cation for use in alkalosis, in the same way that sodium lactate with a disposable anion is used in acidosis. Ammonium chloride has been used but continuation of this practice appears inadvisable until it can be shown that increased ammonium concentration in the systemic circulation is non-toxic.

The management of water and electrolyte disorders must inevitably change as knowledge of water and electrolyte metabolism advances. These instructions and the chart may therefore require modification in the light of future research. However, it is felt that they embody, in as simple form as the subject allows, the essentials of modern management of these disorders.

SUBACUTE NON-SUPPURATIVE THYROIDITIS

TREATMENT WITH CORTISONE AND CORTICOTROPHIN

G. Izak
M.D. Budapest
FIRST ASSISTANT

Y. Stein
M.D. Jerusalem
SECOND ASSISTANT

DEPARTMENT OF MEDICINE B, ROTHSCHILD HADASSAH-UNIVERSITY HOSPITAL, JERUSALEM

Beneficial effects of cortisone and corticotrophin in subacute non-suppurative thyroiditis have been reported by Krupp et al. (1951), Crile (1952), Crile and Schneider (1952), Clark et al. (1953), Teitelman and Rosenberg (1953), Hunter and Sheehan (1954), Benjamin (1955), and Kraft and Wolf (1955).

The ætiology of non-suppurative thyroiditis is unknown, but a virus infection has been suggested (Crile 1952). Pyogenic bacteria have been cultured from suppurative thyroiditis (Thorn and Forsham 1952).

The histological picture of non-suppurative thyroiditis is characterised by the disruption of the acini and by the escape of colloid into the interstitial spaces, where pseudotubercles, giant-cells, and polymorphs are found. These changes are diffuse and usually involve both lobes of the thyroid gland. The lesions gradually disappear, leaving normal thyroid tissue in most cases (Crile and Hazard 1951), but myxœdema (McConahey and Keating 1951) has been reported as a late sequel.

We report here 6 cases of subacute non-suppurative thyroiditis, of which 5 were treated with either corticotrophin or cortisone. Thyroid function was determined by the uptake of radioactive iodine by the thyroid gland and by the excretion of radioactive iodine during and after the disease for up to fourteen months.

Summary of Cases

The history, clinical features, and laboratory findings differed only slightly from case to case and may therefore be presented jointly.

Symptoms and Signs

All the patients were women aged 35–64. In 3 of them the onset of thyroiditis was preceded by an upper respiratory infection one to two weeks earlier. The main complaint was sharp pain at the lower anterior region of the neck, radiating in some of them up to the retro-auricular area. The pain was aggravated by swallowing. There was intermittent pyrexia of 100·4–104·0°F for two to six weeks before admission.

On physical examination all the patients appeared seriously ill, being apprehensive and sweating profusely, with a pulse-rate of 100–120. In some of them a fine tremor of the fingers was observed. In all the patients a diffuse moderate enlargement of the thyroid gland was palpable. The gland was exquisitely tender and firm, and in some patients the skin overlying the gland was reddish, swollen, and hypersensitive. In 2 patients enlargement of cervical lymph-nodes was found. No other pathological signs were noted.

decontrol on such lines as inadvisable if not impossible, the committee concentrate usefully on the means whereby control may be exercised with more knowledge and therefore more delicately and fairly—as indeed has latterly happened to some extent. So that funds may be better allocated and better used, they strongly recommend the development of departmental costing—which will require the willing cooperation of those concerned with hospital administration, not least the doctors. But they well recognise that hospital costs alone do not necessarily reflect the efficiency of hospital management, and the need to find better indices for measuring efficiency is one of the reasons leading them to their important recommendation that the Health Departments should set up a research and statistics department to act as their intelligence branch. This department would consider what information is now lacking and how it can best be got.

But an intelligence branch, helpful though it will be, is not a brain; and the committee has not brought out the fact that the N.H.S. has never had, and still lacks, a policy by which a proper balance between its separate parts is decided and then achieved. At several points Mr. GUILLEBAUD and his colleagues show themselves fully aware that prevention is cheaper than treatment, and that treatment in the home is often cheaper than treatment in the hospital; but only Sir JOHN MAUDE, in his reservation, explains how the present system weights the scales against a reasonable economy. The committee repeatedly urge that people in different parts of the N.H.S. should see the service as one; and they believe (we hope rightly) that habits of cooperation will grow; but they are asking rather a lot of human nature when they suggest that those who run the hospitals so devotedly should remember that whatever they can save may go to balance overspending on something else, such as the pharmaceutical service, and is "not necessarily 'lost' to the National Health Service as a whole." Anyone determined to economise by altering the balance in favour of preventive and domiciliary services would have to recognise that, as the *Times* puts it, "at too many critical points the health service as now organized lacks built-in incentives to economical and efficient administration."

Hospitals are a necessity, and we must not rest until a very much higher standard is achieved in many of those we have today. But this does not mean that the hospital services as a whole ought to go on expanding, bit by bit and year by year. At present, even hospitals that know that they could contract find it hard if not impossible to get into reverse. Demand may fall off with diminishing population, or because of preventive or therapeutic advances: the lightening of the load on children's beds in many populous areas is an obvious example. But from within the hospital the process of cutting down beds and services looks far too much like defeat and far too little like the victory it should be acclaimed to be. Even the distant signs of its happening are a matter for concern: the consultant does not like it to be known that he has difficulty in filling his beds; the matron, the administrator, and the caterer have all been taught to look forward to the day when their hospital will be increasing rather than reducing its complement (their very remuneration is related to the number of beds), and any suggestion of contraction is discouraging and disconcerting. The whole service, in fact, is geared to move only one way—toward expansion. It is to the financial advantage of each general practitioner to have, within reason, as many patients as possible on his list; it is to his advantage, too, to pass as many as possible on to the hospital; and it is to the advantage of the hospital, and everybody in it, to welcome the cases when they arrive, to build up a good rate of occupancy, to develop a larger and better hospital service, and so on. The practices that govern methods of remuneration have been evolved with great care: they are designed to avoid salaries for general practitioners and to preserve freedom for the consultant and a measure of flexibility in the number of sessions assigned to him. It is, too, entirely reasonable to relate salaries of senior categories of administrators and matrons to the size of the hospital in which they work. But we should not forget that when these criteria were evolved it could be taken as axiomatic that the more hospital services we possessed the better. In some areas and for some services this is still, of course, very true; but in others it is true no longer.

With all respect to Sir JOHN MAUDE and others who are anxious for unification of the services under one authority, we would say that it is not the existence of separate machinery that is decisive; for separate machinery in some sense there must be. What may matter more is the fact that the incentives, financial and other, of those who work in the different parts of the service have been allowed to evolve independently, and that nothing has yet been done to solve the problem of fitting them together. We should like to have seen in the Guillebaud Committee's report some indication of the kind of experiment that might be made, which would point the way towards a solution. Were it possible to take a single area—a county borough for instance—and try an entirely different set of financial arrangements, important results might follow. To show how different they could be, let us imagine an extreme case. Suppose that the remuneration of general practitioners in a given area were rearranged so as to involve some deduction in respect of cases passed into the care of the hospital, and a corresponding increase in respect of those treated at home (it might not be impossible to work out a formula); suppose too that the remuneration of the consultants in the area were determined, not by reference to time spent at the hospital, but partly by a fixed rate in respect of availability, and partly by reference to the number of domiciliary visits paid; and suppose that all in administrative positions were paid in accordance with grading or scales which bore no relation to the importance or size of the hospital but on the contrary carried a bonus touched off by any recognisable diminution in the rate of hospital admissions in the community. Suppose all these things, and leave the experiment to run for three or five years, what should we expect to see? Can we doubt that there would be some lessening of the emphasis on hospital services? Though the particular arrangements we have outlined might some of them do more harm than good, they would almost certainly alter the existing balance between hospital and domiciliary work. The existing balance is not necessarily right and it is not unalterable.

find a similar small majority of vaccinated children among those who later contract poliomyelitis In the recent outbreak, poliomyelitis in children of school age was in fact divided about equally between the vaccinated and the unvaccinated smallpox vaccination in infancy evidently does not alter the incidence of poliomyelitis in the age group 5–15 Among the younger children, however, constituting 25% of the cases, the picture is quite different since 1946 there have been 21 cases of paralytic poliomyelitis in the unvaccinated children under 5 years old, but only 4 among the vaccinated This contrast becomes still more striking if we confine our attention to the children under 3½ years old, who were effectively vaccinated in infancy In that age group there were 19 cases of paralytic poliomyelitis, as follows

Case no	Sex	Age at onset of poliomyelitis	Vaccination state	Result	Remarks
1	M	6 wk	No	P 2	
2	F	5 mth	Yes	Died	Died 4 days after vaccination
3	F	8 mth	No	Died	
4	M	11 mth	No	P 2	
5	M	1 yr 2 mth	No	P 3	
6	M	1 yr 2 mth	No	P 2	
7	F	1 yr 3 mth	Yes	P 2	Onset 14 days after inoculation for diphtheria and whooping-cough
8	F	1 yr 3 mth	No	P 3	
9	F	1 yr 6 mth	No	P 3	
10	M	1 yr 6 mth	No	Died	
11	F	2 yr 1 mth	No	P 3	
12	M	2 yr 2 mth	No	P 1	
13	F	2 yr 6 mth	No	P 1	
14	F	2 yr 6 mth	No	P 1	
15	F	2 yr 11 mth	No	P 3	
16	F	3 yr	No	P 3	
17	F	3 yr 4 mth	No	P 3	
18	M	3 yr 6 mth	No	P 1	
19	F	3 yr 6 mth	No	P 1	

Note P 1—Slight paralysis P 2—Moderate paralysis P 3—Severe paralysis

Thus in children under 3½ there were 17 cases of paralytic poliomyelitis (2 fatal) among the unvaccinated, and to these should be added the fatal case (no 2) in which the child died four days after vaccination, at a time when vaccination could not be expected to protect her The correct figure for unprotected children is therefore 18 cases with 3 deaths, whereas for the vaccinated the corresponding figure is 1 case with no deaths

The vaccinated child (no 7) was a girl who had been vaccinated at 6 months in the right leg there had been a severe reaction and (according to the mother) the leg had "gone septic" She was later immunised against diphtheria and pertussis, and at 1 year 3 months she developed paralysis of the left leg, fourteen days after the third injection of the combined vaccine into that limb According to current views this injection may have precipitated poliomyelitis with paralysis, in what might otherwise have been an abortive case

The figures for all cases of paralytic poliomyelitis under 15 years of age, in the period 1946–55, are summarised in the following table, which displays the difference between age groups 0–3½ and 3½–15

Age (yr)	Vaccinated	Unvaccinated	Proportion of poliomyelitis patients vaccinated
0–1	*Nil*	4*	*Nil*
1–3½	1	14	7%
3½–5	3	3	50%
5–15	18†	16†	53%†

* 1 of these children had been vaccinated but died from poliomyelitis four days afterwards

† Approximate figures

During the same period there were 34 cases of paralytic poliomyelitis at ages over 15 None of these patients had been vaccinated within recent years

Comment

The fact that, in this area during these ten years, most of the cases of paralytic poliomyelitis under school age have been in unvaccinated children might be explained in four ways

1 The numbers are small, and the difference demonstrated might be due to chance Personally I am disinclined to accept this explanation, for I have found similar vaccination histories in the cases from three other county districts admitted to our local infectious diseases hospital, where poliomyelitis patients were under my care or observation for the period under review My reason for not including these in my analysis is that these districts were outside my area and I was unable to make personal investigations

2 A recent reduction in the proportion of infants who are vaccinated might account for my findings Supposing, for example, that primary vaccination had virtually ceased in 1950, we should have no difficulty in explaining why so few poliomyelitis cases under 5 years of age have a history of vaccination But in point of fact, though the incidence of paralytic poliomyelitis has risen somewhat in recent years, the primary-vaccination rate has remained fairly constant, as is shown by the following figures

Year	Primary vaccination rate (%)			Poliomyelitis cases under 5 years of age
	Walton and Weybridge (1954 population 40 320)	Chertsey (1954 population 32,640)	Bagshot (1954 population 14 480)	
1955	60	64	50†	9
1954	60	64	47	Nil
1953	45	60	49	1
1952	57	55	53	Nil
1951	55	51	51	1
1950	51	40	47	1
1949	51	30	32	6
	County rate available only *			
1948		46		Nil
1947		57		6
1946		56		1

* The district primary vaccination rate is found to approximate to the county rate over the years 1946–54

† Estimated

3 The difference in incidence of poliomyelitis in vaccinated and unvaccinated children might possibly be related to the child's family or social or geographical circumstances Thus it might be argued (*a*) that parents who take the trouble to have their children vaccinated will also take the trouble to keep them away from infection or (*b*) that children are more likely to be vaccinated if they belong to small families, whose members will be less exposed to poliomyelitis because they have fewer brothers and sisters Neither of these explanations appears likely here

The area is one where social conditions are generally good, and nearly all the children with poliomyelitis have come from homes where they were well looked after

In social class, the fathers of the 25 children under 5 years of age who contracted paralytic poliomyelitis may be roughly classified as professional 5, clerical 5, skilled factory workers 7, labouring 8 The average number of children in these families was 2 6, and of the unvaccinated patients 2 were "only" children

For the fathers of the 25 children over 5 years of age for whom I have similar information, the corresponding figures are professional 5, clerical 7, skilled factory workers 8, labouring 5 In the families of the vaccinated children over 5 years of age the average number of children was 2 4 and in those of their unvaccinated coevals it was 2 3

Actually, if social or geographical factors introduce a bias into the results, one might expect this to be in the opposite direction to that found, for the general belief is that the children of the well-to do are more liable to acute hæmorrhagic leucoencephalitis involving the white matter of the entire central nervous system Atypical pneumonia, with a mononuclear-cell exudate and scattered pulmonary necroses, was also present Post mortem diagnoses of the neurological conditions associated with varicella are too few to substantiate the varied clinical diagnoses which have been made, although certainly many of them appear to be acute disseminated encephalomyelitis In that respect, therefore, this example of acute hæmorrhagic leucoencephalitis as a complication of varicella supports Russell's hypothesis Fowler and French[7] also noted the association with atypical pneumonia Although Lander failed to isolate a virus from either lungs or skin, he inclines towards a virus as the cause, and he suggests that *the disease may* develop after infection by a number of apparently unrelated viruses

PULMONARY EMBOLISM AND 5-HYDROXYTRYPTAMINE

ONE of the puzzles about pulmonary embolism has been the disproportion between the size of the embolus and the subsequent clinical signs When a large embolus blocks a main branch of the pulmonary artery, the results are fatal or very grave But serious circulatory collapse can be produced by an embolus which the subsequent clinical course shows to be quite small The stimulation of pressor reflexes in the lung has been blamed for these widespread symptoms, but no one is really satisfied with this explanation The possibility that a humoral agent might be released at the site of the embolism has also been considered, and recently Smith and Smith[8] have suggested that 5 hydroxytryptamine (5 H T) (serotonin) is the humoral agent responsible 5-H T has been much discussed lately because of its connection with malignant carcinoid tumours of the alimentary tract (argentaffinoma) Patients with these tumours may have a typical syndrome evoked by the 5 H T secreted by the tumour, and the detection of 5 H T or its degradation products in blood or urine during these attacks can be used for diagnosis[9] But, before serotonin was connected with carcinoid tumours, it had been identified as a vasoconstrictor liberated when blood-platelets are lysed in the first stage of clot formation[10] Normally this is only a local action, Udenfriend and Weissbach,[11] for example, showed that the 5 H T liberated is rapidly inactivated, and so long as platelets are intact, 5 H T does not appear It occurred to Smith and Smith that many of the circulatory symptoms of pulmonary embolism resemble those attributed to the secretion of 5 H T in patients with abdominal carcinoid tumours Since there is more or less extensive blood-clotting in pulmonary embolism, both in the vessels and in the infarcted area of the lung, significant amounts of 5-H T may be released, and the Smiths examined this possibility by investigating the results of experimental pulmonary embolism in cats

They allowed blood from the animal to clot spontaneously in a thin film, after one hour the clot was divided into fragments with an average diameter of 2 mm , the fragments were suspended in 1–2 ml of saline solution and injected intravenously This injection caused extensive blockage of the pulmonary arterial bed The effect of this blood clot embolism was a steep fall in blood pressure that lasted for some time the cardiac pulsations became feeble and the heart rate was often slowed at first, later there was a period of hypertension and rapid pulse rate For comparison they injected a similar suspension of starch granules, this either had no effect or caused a transient but profound fall in blood pressure, with cardiac irregularities—a pattern of response quite different from that produced by the injection of blood clot fragments The injection of 10 µg of 5 H T, however produced a response similar in pattern and sequence to that following the blood clot emboli In further experiments to gather more information about this action most 5-H T was found in the lysed buffy layer of blood though considerable amounts were present in the serum and the clot itself Injection of 5 H T or blood clot directly into the right auricle caused a sharp rise of blood pressure in the pulmonary artery, and these and similar experiments suggested that this was the main action of 5 H T If the injections were made so as to by pass the lung beds, the vascular effects were only slight The possibility that histamine or acetylcholine might be causing these vascular changes was excluded by repeating the experiments in the presence of specific antagonists The blood-clot experiments were also repeated in the presence of dibenamine and yohimbine, which are known to antagonise the vascular actions of 5 H T , and of cocaine which potentiates them These drugs acted in the same way with the blood clot injections as they did with 5 H T injections Finally, cats were given 2 ethyl 3 nitroindole, which is known to be an antimetabolite of 5 H T , when blood clot suspension or 5 H T was injected into these treated animals, there was little change in arterial pressure

All these experiments suggest that the release of 5 H T by clotting blood at the site of embolism, or elsewhere in the affected tissue, may play a part in the clinical picture that appears Since experience has shown that heparin often diminishes the unpleasant after effects of pulmonary embolism, Smith and Smith carried out some experiments to see whether heparin antagonises the action of 5 H T Injection of 5-H T into a previously heparinised animal was much less effective in lowering the arterial blood pressure, and in vitro experiments showed that heparin reduced the action of serotonin on the rat colon preparation

These findings raise the question of possible therapeutic measures for reducing or neutralising the action of 5 H T Heparin is already used, and the Smiths' experiments confirm its value 5 H T antagonists might be used, but dibenamine is an anti adrenaline drug still in an experimental stage, and yohimbine is hardly suitable for general use The 5 H T antimetabolite, 2 ethyl 3 nitroindole, takes twelve to forty eight hours to become effective after administration by mouth, and such a delay would make it useless Nevertheless, this work points to a new approach to the treatment of pulmonary embolism, and more appropriate drugs may soon be available

FOOD-POISONING AND DRIED MILK

MOST samples of unpasteurised milk contain *Staphylococcus aureus*, and some of the organisms are strains commonly associated with enterotoxic food poisoning Staphylococci are at least as common on the bovine teat as they are on the human hand and equally difficult to remove Many cows suffer from staphylococcal mastitis, and indeed it is possible that this infection is commoner than it was, owing to the widespread use of penicillin for the eradication of streptococcal mastitis With all the care in the world, some multiplication of bacteria in milk between the teat and the tea cup is unavoidable Nevertheless, only 2% of the recorded outbreaks of food poisoning in 1954 were traced to raw milk and in previous years even fewer[1] The probable reason for this anomaly is that enteritis is caused not by the staphylococci themselves but by the enterotoxin which they produce when they multiply in a suitable medium If milk is kept under conditions which favour the formation of enterotoxin, there will be a simultaneous multiplication of those other bacteria which cause souring and the milk will become unpalatable It is possible too,

Urinary bilirubin	Neg		±	Neg		
Benzidine test (urine)	Neg	Pos		Pos		
Urea clearance						Normal
Naphthalene derivatives in urine	Neg					

On 4th day albumin/globulin ratio in serum serum-chloride, serum sodium, serum phosphorus, and serum-calcium levels, and plasma alkali reserve were normal

On 6th day bone marrow showed increased erythropoiesis

The differential white-cell count was always normal except for slight left deviation from 3rd to 5th day

Dec 6—She was still icteric but felt well, apart from tenderness in the left kidney region (complained of as abdominal pain) The colour of the urine reverted to dark-brown, and the number of red cells remained about constant The spleen was not palpable

Dec 7—She was no longer icteric Her urine was bright-brown, but she passed less than half a litre in twenty four hours Her fluid intake was restricted.

Dec 8—The red cell count began to rise, and the urine was yellow and normal in amount

From *Dec 9* convalescence ensued, the girl still complaining of slight pain in the kidney regions for some days

From *Dec 18* to *Dec 20* she complained of heartburn and epigastric pain. Six times she vomited 50–100 ml of bright-red bloody fluid, reporting that the fluid had "somehow suddenly accumulated in her mouth" Examination of mouth, nose, pharynx, and larynx, and radiography of œsophagus, stomach, and duodenum revealed no source for this bleeding It remains doubtful whether this episode has any connection with the intoxication.

The results of investigations are shown in the figure and in table I

Review of Literature

Earlier Cases

Many cases of naphthalene and naphthol poisoning are recorded in the older literature, but in the absence of modern facilities the interpretation of symptoms and signs was inadequate and mortality was high

9 of such cases (Goetze 1899, Nash 1903, Prochownik 1911, Heine 1913, Wiedow 1914, and others) were reviewed by Lewin (1893), Kraus and Brugsch (1923), and Zuelzer and Apt (1949) In at least 2 of them no blood studies were reported 7 of them were caused by therapy, 1 was an accidental moth-ball intoxication, and 1 was a murder 3 were fatal The outstanding symptoms were general urinary symptoms (dysuria, pollakisuria, oliguria, and transient anuria), 7 cases, dark urine, 4 cases, hæmoglobinuria, 3 cases, jaundice, 4 cases, and neurological symptoms (restlessness, disorientation, coma, and convulsions), 4 cases

Gastro intestinal symptoms and eczematous reactions to the topical application of naphthalene were well known Although the darkening of urine was recognised as a symptom—"the darkening of the urine starts usually about five hours after the administration of naphthalene" (Lewin 1893)—this was not appreciated as a sign of acute hæmolysis

Recent Cases

The findings of Ullmann (1947)* together with those of the later reports and ours are summarised in tables II and III

Treatment in all cases was by blood-transfusion Some workers added alkalis and antibiotics and we used cortisone and vitamin B_{12} as well

Mackell et al (1951) and Zuelzer and Apt (1949) also made experiments Mackell et al (1951) tested the hæmolytic activity of naphthalene and its metabolites (the naphthols and naphthoquinones) and found that in

Special Articles

NATIONAL HEALTH SERVICE

Recommendations of the Guillebaud Committee

IN May, 1953, the Health Ministers appointed a committee

> " To review the present and prospective cost of the National Health Service, to suggest means, whether by modifications in organisation or otherwise, of ensuring the most effective control and efficient use of such Exchequer funds as may be made available, to advise how, in view of the burdens on the Exchequer, a rising charge upon it can be avoided while providing for the maintenance of an adequate Service, and to make recommendations "

The chairman was Mr C W Guillebaud (now reader in economics in the University of Cambridge), and the members Mr J W Cook, F R S (principal of the University of the South West), Miss Anne Godwin (a member of the council of the Trades Union Congress), Sir John Maude (formerly secretary to the Ministry of Health), and Sir Geoffrey Vickers, V C (treasurer of the Medical Research Council) All these have signed the report published last week,[1] but reservations are appended by Miss Godwin and Sir John Maude

Cost of the Service

In reviewing the present and prospective cost of the service the committee have made use of a memorandum prepared at their request by Prof R M Titmuss and Mr Brian Abel Smith, PH D Summarising this in our last issue, Dr Abel-Smith said that the real increase in the cost of the N H S since 1949–50 has been negligible in view of changes in the population, and that the share of the community's resources used on the service has been declining The committee reproduce the figures leading to this conclusion

The General Structure

The committee reject the suggestion that a National Board or Corporation should be appointed to administer the N H S

Health Authorities

Nor do they want to see the health services unified by the appointment of statutory ad-hoc health authorities which would administer all of them—hospital, practitioner, and local authority services In their view the only form of major reorganisation which calls for serious discussion is one which would add responsibility for the hospital service and/or the executive council services to the present duties of the local health authorities

But they do not feel that a convincing case has been made out for transferring the hospitals to the local authorities

> " Some form of regional authority will always be required for the efficient planning of a national hospital service, and if the service were to be managed by the local authorities, Joint Boards (or some similar bodies) would be necessary to carry out this planning function The service would then be administered through the Health Departments, Joint Boards, local authorities, and presumably hospital managing committees This administrative structure would not be calculated to improve the coordination of the service either at the national level or at the officer level, and would simply create new problems in the relationship between Joint Boards and local authorities Bearing in mind also that some local authorities themselves would be reluctant to accept responsibility for the hospital service that the bulk of the medical profession would be opposed to the suggestion, and that the financial burden would be intolerable unless the Exchequer grant were so substantial that it would render local government responsibility merely illusory, we feel confident that, whatever the merits of the proposal, it is not a practical proposition at the present "

The proposal that maternity, tuberculosis, chronic sick, and infectious diseases hospitals should be transferred to the local authorities is likewise dismissed, since it would *disrupt the hospital service* Sir John Maude would like to see the work of executive councils given to the local health authorities as a step towards unification

General Conclusion

The committee hold that the structure of the N H S was framed broadly on sound lines, and any fundamental change would be premature

> " It is still a very young service and is only beginning to grapple with the deeper and wider problems which confront it *What is most needed at the present time is the prospect of a period of stability*, in order that all the various authorities and representative bodies can think and plan ahead with the knowledge that they will be building on firm foundations Some of the strains and stresses of the National Health Service are attributable to the difficulty experienced by many, who had *grown up under the old system, when called upon to* operate a service administered on different lines Longer experience of the working of the Service and the gradual emergence of a new generation may make comparatively simple many things which now appear difficult or impracticable

An " Adequate " Service

Referring to the word " adequate " in their terms of reference, the committee point out that the amount of the national resources allocated to the N H S must be determined by the Government, the development of the service being one among many public tasks in which objectives and standards must be realistically set and adjusted both to means and to needs As in education, the aim must be to provide the best service possible within the limits of available resources

> " If the test of ' adequacy ' were that the Service should be able to meet every demand which is justifiable on medical grounds, then the Service is clearly inadequate now, and very considerable additional expenditure (both capital and current) would be required to make it so "

The Hospital and Specialist Services

Teaching Hospitals

One of the dangers of a national hospital system lies in uniformity, and the committee (except Miss Godwin) see distinct advantage in preserving the separate status of the teaching hospital They think it would be short-sighted now to subordinate these institutions, " upon which so much depends for the future development of the service," to the regional boards But they emphasise the board of governors' responsibility for coöperating fully with other organisations in the service, and " for the most efficient and economical management within the teaching hospitals themselves " For Scotland no change is proposed

Powers and Functions of Hospital Authorities

For administration of a service dealing with more than 3000 hospitals in England and Wales and some 400 in Scotland, two levels of management are considered essential " The service undoubtedly requires both regional authorities covering areas large enough for purposes of planning and general supervision, and also group management authorities with responsibility for the day to-day running of the service " It should be made clear that regional boards are responsible for *exercising a general oversight* and supervision over the administration of the hospital service in their regions, and the Ministry of Health should leave this task to the boards and not undertake it over their heads

TETANUS

RICHARD BATTEN
F R C S

LATE REGISTRAR, BIRMINGHAM ACCIDENT HOSPITAL

THE urgent problem in established tetanus is the control of convulsions Hitherto treatment has consisted in sedation with central depressants or in relaxation with drugs of the curare type, or in both

Central depressants are likely to depress respiration, but Forbes and Auld (1955) report 15 cases treated thus without a death, and Grant and McNeilly (1953) describe in detail the successful management of 1 case with thiopentone and pethidine

Relaxants, advocated by so many workers in recent years, are likely to be needed in such large doses that the diaphragm also is paralysed This in turn demands tracheotomy and positive pressure respiration

Tracheotomy—Galloway and Wilson (1953) found that tracheotomy diminished spasms and facilitated the sucking out of secretions Impressed with the improvement that followed routine tracheotomy and positive pressure respiration in bulbar poliomyelitis Lassen et al (1954) recommended curare for tetanus The paralysed and anæsthetised patient was then treated in the same way as one with bulbar poliomyelitis On this regime 3 of their 4 patients with severe tetanus survived Other workers have had variable success with tracheotomy, pulmonary complications apparently not being reduced, though sudden respiratory occlusion can be controlled, Continuous attendance by a doctor, however, is almost essential, and a great strain is thrown on the nurses

Other drugs which may be important in the management of tetanus are chlorpromazine (Bodman et al 1955) and the cortisone group (Lewis et al 1954) Their advantages are still doubtful, and only a few reports have been published

Antitetanic serum—In published cases the quantity, route, and timing of antitetanic serum have been so varied and so unrelated to the outcome that its value seems uncertain Theoretically it seems to be vital for neutralising circulating or unfixed toxin immediately, but convincing experimental and clinical evidence that it does so is lacking Given prophylactically it may be of more certain benefit, but Littlewood et al (1954) report a fatal case of tetanus in a boy who had 1500 units of antitetanic serum two hours after the accident, and anaphylactic deaths from antitetanic serum are not very rare

Management of the *electrolyte balance* has been well studied by Wilson and Care (1955)

Prognosis

The length of the incubation period seems to be clearly related to the severity of the disease, but, as our case suggests, a short incubation period need not make a fatal outcome certain Reported recoveries when the incubation period was less than five days are certainly very few

Case-report

On Aug 22, 1955, a boy, aged 7 years, was playing with his friends throwing lumps of earth at each other He was standing beneath a lamp post when one of the boys shook it, and a small piece of broken glass fell and pierced his scalp His mother found a very small scalp wound, which she did not think worth treatment Next day he walked with a "funny" posture of his shoulders and his jaw became stiff He had a definite convulsive fit at home that night, just thirty six hours after the injury He now could not swallow, and next morning his pillow was soaked with saliva It seems certain that for many weeks he had had no other injury, because his mother insisted that he always presented the most trivial injury to her for inspection and commiseration

Examination and Diagnosis

On admission to hospital on Aug 23 he was pale, looked ill, and had severe painful trismus, a classical risus sardonicus, and neck rigidity His rectal temperature was 99 8 F Tetanus was tentatively diagnosed, and a very guarded prognosis was given to the mother, it was still hoped that the condition might be due to meningitis Lumbar puncture however, produced clear cerebrospinal fluid with normal constituents

Treatment and Progress

Antitetanic serum 100,000 units was given intravenously after an intramuscular test dose of 1500 units The same evening the boy seemed better, his jaw was less tightly clenched and he sat up to play with his toys when visited by his parents, to whom a brighter prognosis was now given In the morning, however, this opinion had to be revised, for during the night a convulsion left him with severe opisthotonos, and next morning he had powerful and almost continuous spasms Rectal thiopentone 1 g in 5% solution produced sufficient relaxation for a polythene cannula to be inserted into the saphenous vein at one ankle to deliver above the knee, thiopentone continuously at the rate of 2 25 g in 1 5 litres of 4 2% glucose in 0 18% saline solution every twenty four hours (0 75 g per 500 ml bottle of glucose and saline solution) Tracheotomy was considered at this point, but, since the reflex spasms were completely controlled with thiopentone, relaxants and controlled respiration appeared unnecessary Continuous anæsthesia was thus maintained for fifteen days The amount of thiopentone needed to relax the hypertonic muscles was 1-2 g in twenty four hours Even then the child continued to have trismus, and the tonicity of his muscles varied from full opisthotonos to mild tightness of the recti abdominis muscles Thrombophlebitis developed in the leg on the fourth day, the cannula was removed, and a new cannula was inserted into the opposite ankle to deliver thiopentone directly into the inferior vena cava This ran successfully for a week and then slipped out unexpectedly owing to the boy's restlessness A third cannula was inserted at the wrist to deliver near the shoulder and ran until it was no longer needed The amount of thiopentone given was controlled by altering the concentration in the bottles as a long term measure or, for quicker action, by injecting a few ml of 2 5% thiopentone into the rubber tubing near its junction with the cannula

Nutrition

Nutrition was maintained partly by the intravenous glucose and saline solution and partly through a nasal catheter to the stomach This catheter was passed with the help of 30 mg of intravenous suxamethonium chloride and was changed by the same technique after ten days By this route a continuous drip of nutrient mixture was supplied, each 500 ml bottle containing 1 pint of milk, 2 switched eggs, 1 oz of sugar, and 1 oz of 'Casilan' to a total of 1 5 litres in twenty four hours, providing 1000 calories Vitamins were added to this mixture in suitable doses The serum electrolytes were estimated at intervals The only abnormality was a lowered serum potassium level on the sixth day, this was corrected by adding potassium chloride to the intravenous fluid

Respiration

Respiration was at first obstructed at intervals when trismus was so severe that the rubber airway was occluded A metal airway of the Waters type was found to resist the boy's bite, and its side tube allowed the pharynx to be sucked clear Atropine gr $^1/_{200}$ three hourly reduced bronchial secretion but increased the viscosity of secretions from nose and throat, making laryngeal toilet more difficult Sulphadimidine via the gastric drip and intramuscular penethamate hydriodide ('Estopen') were given to prevent pulmonary infection Frequent suction was necessary via the nose and mouth to prevent saliva and nasal secretions from running down the trachea, but suction increased secretion and therefore had to be limited On the fourth day of anæsthesia

experimentally in a limited number of hospitals "Whilst we would agree that the subjective accounts must be retained at least for the time being, we would suggest that their retention be reviewed at a later date"

> "We trust that all concerned with hospital administration —not least the doctors—will co operate to the utmost in order to make a success of this vital aspect of hospital management We should regard it as unfortunate if opposition to the compilation of departmental costs or similar data were to be based on the mistaken idea that any conclusions could be drawn from these figures as to the professional standards or competence of doctors in different hospitals"

Voluntary Contributions

The committee regard it as entirely appropriate that appeals for voluntary contributions should continue to be made by voluntary bodies (for purposes agreed with the hospital concerned) but not by the statutory boards or committees They see no reason why hospitals should not (as many now do) spend endowment moneys on purposes for which Exchequer money could properly be used "It seems to us that the continuance and further expansion of voluntary service is one of the surest ways of maintaining the essential humanity and vitality of the hospital service and preventing the development of that enemy of human welfare—institutionalism"

A Boarding Charge?

Having regard to the relatively low yield likely to be obtained from a hospital boarding charge (after all the probable exemptions have been taken into account), and to the practical difficulties, the cost of collecting the charge, and the strenuous opposition which would be aroused on humanitarian grounds, the committee do not advise its introduction

Staff

Administrative Staff—The committee regret that there should still be no provision nationally for recruitment and training of hospital administrators and recommend such provision as soon as possible

Consultants Whole time or Part-time?—There is, in the committee's view, a valid case under existing conditions for the retention of part-time consultant appointments in addition to whole time appointments

> "We consider it very desirable, however, that Regional Boards should be free to appoint whole time consultants in cases where it is deemed to be necessary in the interests of the service We trust that joint consultation between Regional Boards and the medical consultative committees will lead to agreement between the Boards and the medical profession, and will prevent the emergence of differences of opinion over the conditions of appointment such as have been known to occur in the past
>
> "We are also of opinion that it is undesirable that the financial arrangements relating to the consultant service should be such as to provide a financial inducement to a consultant to apply for a part time rather than a whole time appointment"

A New Specialist Grade?—They welcome the suggestion that, as part of the reorganisation of hospital medical staffing, provision should be made for a new specialist grade, below the grade of consultant, which would offer a permanent position in the career structure of the hospital service

The Medical Administrator

On day-to-day medical administration the committee endorse the views of the Committee on Internal Administration of Hospitals (1954)

> This did not favour group medical superintendents, but wanted the larger general hospitals to appoint, as part time medical administrator for a few years at a time, a consultant in active clinical practice—his appointment to involve no loss of salary Where no such person could be found the work could be done by a younger man in a new R M O or R S O grade

Amenity Beds and Pay Beds

The committee accept the provision of pay beds and amenity beds—bearing in mind that these represent a very small proportion of the total beds in the N H S They remark that all hospital beds, whether free or not should be fully used, but they do not suggest any change in the calculation of charges for pay beds It would be inadvisable to depart from the principle that "the user of a pay bed, having contracted out of the free hospital service, should pay the full cost "

The Family Doctor

Doctor and Patient

The committee are inclined to agree with the Cohen Committee on General Practice (1954) that in general the N H S has not disturbed the doctor patient relationship

Drugs

They are against the introduction "at the present time" of a limited list of drugs prescribable in the N H S But every effort should continue to be made to keep doctors informed about the cost of prescribing generally The advantages obtainable from full pricing of prescriptions are unlikely to be worth the cost Nor do the committee favour the reintroduction of a returnable cash deposit for containers

Central Register of N H S Patients

The existing Central Register is inadequate, and a central alphabetical index appears desirable for the sake of efficiency, economy, and equity

The Family Doctor and the Hospital

The committee associate themselves with various previous recommendations

> Practitioners should have at their disposal hospital beds where they can retain responsibility for their patients They should be encouraged to do part time work as clinical assistants and in the normal hospital grades Diagnostic facilities (particularly radiological and pathological) should be directly available to them wherever possible The rôle of the out patient department should in the main be consultative The general hospital should be a centre of medical endeavour, where the practitioners have right of entry and can meet their hospital colleagues on terms of equality

Concerned, as they are, with the efficient and economical operation of the N H S, the committee say

> "It is desirable that whenever practicable patients should be treated in their own homes by the general practitioner and the local health services, instead of being admitted to hospital where the running costs are so high, and that when a patient is admitted to hospital, he should be discharged at the earliest possible date, any necessary follow up treatment being provided either in the hospital outpatient department or at home by the general practitioner and the home health services"

Dental and Ophthalmic Services

Dentistry

After speaking of the "acute shortage of trained dental man-power (which appears to be growing more serious each year)" the committee declare that in oral disease the opportunities for preventive work are outstanding They hope that the pilot demonstrations of fluoridation of water supplies will be pressed forward, and they urge increased research, more dental health education, and more efficient dental services for mothers and children They discard a proposal that responsibility for the clinic services should be transferred from the local authorities to the Health Departments, but they say that one of the lessons of the past seven years is that some balance must be kept between remuneration inside and outside the clinics Having pointed out that there seems to be a prima-facie case for employing dental ancillaries, they remark that, whatever is done, we cannot hope for an expansion of the service sufficient to meet all needs

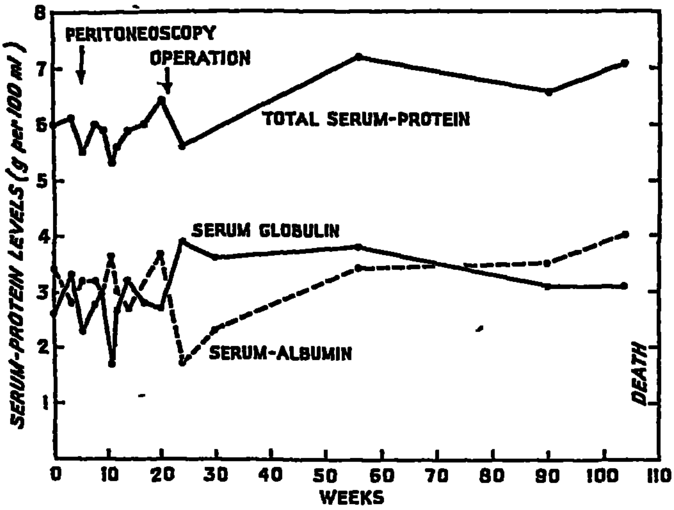

Fig 1—Serum protein levels during illness

On Jan. 10, peritoneoscopy was undertaken by Mr W W Davey, who reported "9 pints of fluid were withdrawn, and good visualisation of the liver was obtained, the anterior sharp edge was rounded with coarse irregularity of the surface and loss of normal architecture Many blood vessels were seen on the surface and there were many recent adhesions between the anterior surface of liver and the parietal peritoneum No superficial hepatic metastases or tubercles were seen the condition is probably acute cirrhosis" These findings were consistent with the clinical diagnosis of Chiari's disease

On Jan 12, treatment was started with phenindione ('Dindevan') 100 mg twice daily, but within twenty four hours the prothrombin time rose from 28 to 75 sec and the treatment was stopped The thymol turbidity was then 9 units, the alkaline phosphatase 16 units, the serum bilirubin 0 2 mg per 100 ml, and the blood urea 20 mg per 100 ml

On Feb 9 prominent, dilated veins on the sides of the chest were noticed, and liver biopsy was repeated This showed engorgement and reticular fibrosis, with dilated, engorged, capillary spaces and inflammatory infiltration in fibrous strands The thymol turbidity was 3 units, the alkaline phosphatase 15 5 units, and the fæcal urobilinogen 27 mg per day

Operation

It was decided that ligation of the hepatic artery might relieve the hepatic congestion no less effectively, and more safely, than a portacaval shunt Mr W W Davey therefore did a laparotomy on April 25 and reported "The spleen was enlarged to twice the normal size, and the liver was adherent to the abdominal wall and to the stomach The portal pressure was not appreciably raised as judged from the appearance of the gastro epiploic veins and the slight bleeding when making the incision The splenic and hepatic arteries were ligated, the latter just proximal to the gastroduodenal artery Both these procedures were difficult because of induration and adhesions" A liver biopsy specimen taken at operation showed "severe fibrosis of irregular pattern with focal hæmorrhage and some regeneration, with slight chronic inflammatory reaction"

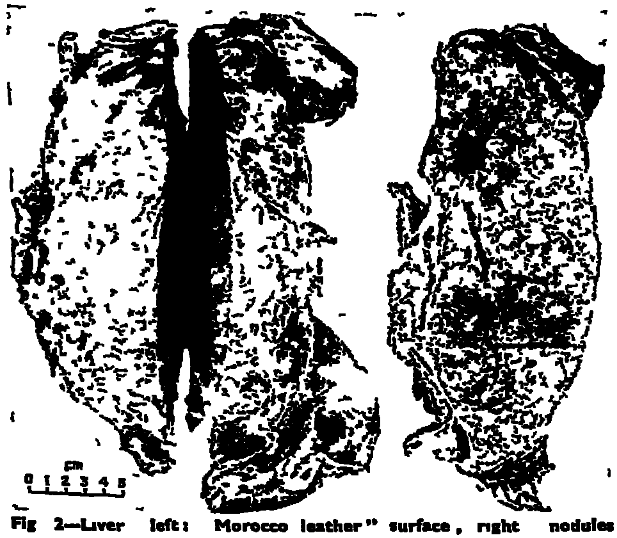

Fig 2—Liver left: "Morocco leather" surface, right nodules of regeneration

Subsequent Progress

After discharge from hospital in June, 1953, the patient continued to attend weekly for abdominal paracentesis, but on Nov 12 he was readmitted with slight hæmatemesis and melæna The veins in the abdominal wall and on the sides of the chest were now more dilated and a barium swallow showed varices at the lower end of the œsophagus He was discharged on Dec 8, and four days later (twelve months after his first admission) the final paracentesis was performed

On Jan 19, 1954, he complained of pain in the breasts and was found to have gynæcomastia, several spider nævi on the face and hands were also noticed There were dilated veins in the flanks, and the liver was hard and nodular

On April 9, the thymol turbidity was 2 units and the alkaline phosphatase 21 1 units He returned to work where he remained until Jan 22, 1955, when he was again admitted with hæmatemesis and melæna Despite blood transfusions his condition deteriorated rapidly and he died in coma on Jan 24

Necropsy (Dr S Robinson)

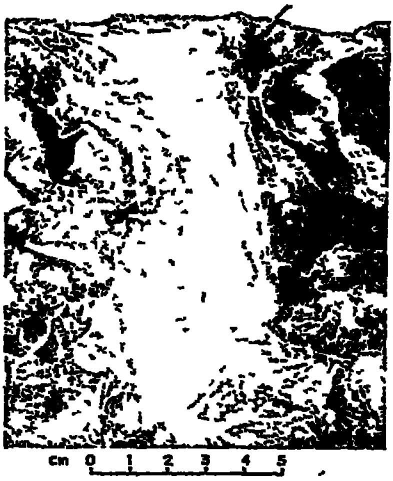

Fig 3—Inferior vena cava, showing fibrosis of adventitia

The *liver* was enlarged (weight 4 lb 13 oz) and firmly fixed to diaphragm, spleen, and stomach by fibrous adhesions bearing many dilated tortuous veins The outer surface was coarsely nodular with a "Morocco leather" appearance (fig 2) The cut surface was mottled with a coarse, grey network of fibrous tissue containing engorged sinusoids and cords of pale yellow surviving liver parenchyma with nodules of regeneration up to 1 cm in diameter (fig 2) The hepatic veins were inconspicuous, and the openings of the left and lower right hepatic veins into the inferior vena cava were completely obliterated, the right upper hepatic vein was blocked by fibrous tissue 1 5 cm from its mouth The *spleen* was slightly enlarged (weight $8^1/_2$ oz) with hyaline fibrosis of the capsule and prominent veins in the adhesions, the cut surface showed engorgement *Heart and blood vessels* the heart weighed $9^1/_2$ oz, and there was œdema of the myocardium There was hypoplasia of the aorta, the circumference of the thoracic portion being 4 cm and of the abdominal portion 3 5 cm There was considerable fibrosis around the adventitia of the inferior vena cava (fig 3) and there were dilated veins in the submucosa of the lower three quarters of the œsophagus with erosion of three veins containing adherent thrombus There were prominent, dilated, tortuous veins in both iliac fossæ and under the skin of the abdomen and back *Stomach* on the anterior wall of the pyloric antrum there was a chronic ulcer measuring 4 × 3 cm which was firmly adherent to the liver and which had several bleeding points in its floor

Adhesions obliterated both *pleural cavities* There were œdema and congestion of the *lungs, brain, kidneys, suprarenals*, and *intestines*

In England Now

A Running Commentary by Peripatetic Correspondents

WHEN the visiting specialist makes a tour of the ward, sister and one of the house-surgeons are in close attendance and behind comes a staff nurse ssh-sshing any patient who dares to so much as breathe noisily A holy hush descends for any doctor and, in a modified degree, for matron's visits Decorum thus prevails during the morning hours, but the noise in a public ward for the rest of the day has to be heard to be believed Conversations are carried on between occupants of beds at opposite ends of the ward probationers retail the latest song hits, community singing is popular, and loud-speakers, tuned eternally to the light programme, add to the din

Many hospitals are built in busy streets Our local infirmary faces a main road, and has a railway shunting-yard behind it and a coach station next door Traffic goes on round the clock and I was surprised to find that after two wakeful nights I hardly noticed it The regular sounds of the ward were much more disturbing My bed was next to a cupboard with sliding doors which seemed to be crashed open and shut about every five minutes all night Screens are rattled about and shut up with a bang Most night-nurses wear shoes that squeak, and the bed of one unlucky patient was next to the bathroom door

Do doctors really believe that, between their visits, the ward is so quiet that you could hear a swab drop ?

* * *

Now that modern mass-production techniques have all but ousted the single-handed preparation of mist , ung , and tab in the little dispensary that once flourished in the lee of every doctor's surgery and chemist's shop, it is, I suppose, old-fashioned to grumble if the names of drugs, as well as the drugs themselves, are mass produced And that is the prospect before us According to the New York correspondent of the *Daily Telegraph* (Jan 20) the baffled boffins of a well-known American pharmaceutical firm have abandoned their self-appointed task of juggling with assorted letters of the alphabet, and turned the whole thing over to an electronic brain

Fed on a diet of word-endings " found to be common in the medical literature of several languages," this machine rejected 22,000 " unsuitable combinations," and then " proceeded to coin 40,000 words," all of a medicinal flavour suitable for drug names Some of the words passed by the machine had also to be consigned by the human editor to the rejects, for the machine is regrettably unable to recognise words that cannot be used in polite conversation

Some of the successful examples such as starycide, platuphyl, chohacyn—certainly carry a vague *soupçon* of the pharmacopœia, though one might be hard put to say just why Certainly they suggest that the heralded new electronic age of innocence will be supremely untroubled by such outdated questions as the meaning of meaning

How doth the lowly *platuphyl*
Avert the psychic pain
Of *starycidal* tendencies
In *chohacyn's* train

* * *

To me, unlike my fellow peripatetic of Jan 14, all airports are much the same airport—they run so much to pattern Were it not for the name picked out in large letters and for striking variations in the temperature I should hardly have known in which hemisphere I was True that Frankfurt had an ornamental lake and waterfalls which might look well floodlit But it was maddening to be set down for three-quarters of an hour in Istanbul and confined within a sort of compound containing only a buffet bar and some inferior toys and jewelry There was a longer, drearier, and stuffier wait at Beirut where the Syrian guards seemed to look at us with the gravest suspicion Still perhaps I exaggerate international monotony At Karachi my wife reported that she had found two Pakistani gentlemen, lightly clad in shorts and vests chattering volubly, and enjoying their lunch while squatting at ease on the floor of the ladies' lavatory I admit you wouldn t see that in England now

Letters to the Editor

HYPERTROPHIC PULMONARY EMPHYSEMA

SIR,—Your leader of Jan 7 follows the familiar pat of articles upon this subject The usual argument f and against its causation by inspiration, expirat coughing, resistance to air-flow, and elasticity (u synonymously with elastic tissue) are set out Then, b convention, the greater part of the article deals with t various physiological function tests in vogue

Your statement that 'any hypothesis should take in account the almost invariable association of hypertro emphysema with bronchial diseases such as chronic bronch or asthma " is misleading Surely it would have been m realistic to have stated that in the ordinary run of p mortem examinations hypertrophic emphysema is alm invariably associated with chronic bronchitis I was unaw that there was any particular association between emphyse and uncomplicated asthma, indeed, emphysema is a unusual finding at necropsy in patients dying from asthma.

The lethal feature of chronic bronchitis is inflammatio of the respiratory unit—namely, the primary lobule an its associated bronchiole Repeated infection leads to progressive lobular and bronchiolar obliteration b fibrous tissue This throws an added strain upon th healthier respiratory units, whose lobules dilate to occupy the spaces previously taken by lobules which have shrunk by fibrosis This mechanism, supplemented here and ther by valvular dilatations, leads to alveolar rupture with a considerable increase in interlobular air drift—in other words, emphysema This process is an inevitable con quence of chronic bronchitis , and the question of whether or not emphysema exists is largely academic, as it inevitably does so, provided the chronic bronchitis i sufficiently severe and lasts long enough If physiological function tests are to be applied as an adjunct to clinical and radiological examination, the most useful in practice are oxygen saturation before and after exercise, and tests of pulmonary function before and after the administration of relaxant drugs when associated bronchospas is suspected

On rare occasions, emphysema develops in the absence of infection Little is known of the pathology in the cases, until detailed studies of the distribution and state of the bronchioles, lobules, blood vessels, and elastic tissue have been made, any explanation of the mechanisms involved is bound to be hypothetical

NEVILLE C OSWALD

London W 1

A PLATELET FACTOR RESPONSIBLE FOR CLOT RETRACTION

SIR,—In the course of platelet transfusion experiment in thrombocytopenic patients it was noted that admin tration of non viable, preserved platelets, although no raising the thrombocyte count, improved the utilisatio of prothrombin and the retraction of the clot[1] Th observation prompted a search for a constituent platelets with the ability to induce retraction of platele poor plasma and fibrin clots Such a factor has bee postulated by Glanzmann[2] and Fonio[3]

Treatment of isolated and thoroughly washed hum or bovine platelets with 75% acetone water v/v or 65 ethyl water v/v mixtures yields an agent which induc retraction of a clot of native platelet free human plas or of purified bovine fibrinogen clotted by thromb This factor precipitates also in ethyl ether at –20 The acetone extract may be freed of thromboplast factor by heating at 56°C for two hours, followed b storage at –20°C for forty eight hours Ethyl eth extracts are free of platelet thromboplastic factor

---

[1] Stefanini, M Unpublished observations, 1955

[2] Glanzmann, E *Amer Pediat* 1918, 88 113

[3] Fonio A *Acta hæmat* 1952, 8, 363

On Nov 25, 1954, further radiographs showed both $\underline{8/8}$ ugh up above the still unerupted $\underline{7/7}$ and corresponding o a dental age of 10 years There was no change of calcifica ion in the remaining teeth during the intervening eighteen months but an apical area had developed on the $\overline{|2}$ From this dental evidence some factor appears to have supervened at about the age of 8 years or over, preventing the full development and calcification of the teeth

Progress and Treatment—Idiopathic hypoparathyroidism was diagnosed in view of the low serum calcium level, high serum phosphorus level, normal radiological appearances of the bones, absence of renal insufficiency, and absence of steatorrhœa Despite the patient's suggestive facies and stature, the case was not considered to belong to the pseudo hypoparathyroid variety (Albright et al 1942) in view of the absence of dyschondroplasia and subcutaneous calcification (MacGregor and Whitehead 1954, Robinson et al 1954) The macrocytic anæmia was noted but examination of the bone marrow at this time was inconclusive Anticonvulsant drugs were withdrawn for a week in June, 1954, and treatment was started with dihydrotachysterol 1 ml (1 25 mg) t d s and calcium lactate gr 25 t d s The former was gradually increased to 20 ml daily, but the serum phosphorus level remained higher than the serum calcium level The Hb increased at first but later decreased again In November, 1954, examination of the blood showed Hb 42% (6 2 g per 100 ml), colour index 1 35, leucocytes 2700 per c mm, mean corpuscular volume 110 c µ, reticulocytes 0 8%, and serum bilirubin level 1 4 mg per 100 ml Sternal puncture showed severe megaloblastic dysplasia of the bone marrow Cyanocobalamin 50 µg was given daily by injection The Hb increased rapidly and after five days there was a reticulocytosis of 8% Calciferol 200,000 units daily was substituted for the dihydrotachysterol and the serum calcium level considerably improved No fit had been recorded since March, 1954, and the patient now felt very well, and the signs of latent tetany had disappeared Further electroencephalograms showed improvement On Nov 4, 1954, there was an alpha rhythm at 9 c p s of moderate amplitude and fair symmetry There was excess diffuse episodic theta activity at 3–6 c p s No specific epileptic waves or focus seen On Dec 10, 1954, the electroencephalogram could be considered within normal limits for the patient's age

Follow up—When seen as an outpatient in February, 1955, the patient's Hb was 100%, serum calcium level 8 4 mg per 100 ml, and serum phosphorus level 11 4 mg per 100 ml

Discussion

The nature of the anæmia is an interesting problem Three main possibilities were considered (1) a true pernicious anæmia, (2) the result of long continued dosage with phenytoin sodium, and (3) the result of the hypoparathyroidism

True pernicious anæmia is rare under the age of 40 Murphy (1939), in 550 patients seen personally, found only 1 aged less than 20 Nevertheless the histamine fast achlorhydria, the typical peripheral blood picture, the frank megaloblastic marrow in October, 1954, and the rapid response to cyanocobalamin point strongly to true pernicious anæmia

As regards phenytoin sodium Hawkins and Meynell (1954) described a case in which a megaloblastic change was thought to have been induced by phenytoin sodium Their patient, however, had free gastric acid The hypoparathyroidism is considered to be the least likely cause While the patient was receiving dihydrotachysterol 20 ml daily, her Hb was decreasing rapidly

After a month's treatment with calciferol there was much improvement in the electroencephalograms which could be considered normal for the first time (the first record having been taken in March, 1953) This suggests a definite relationship between the treatment, which produced a rise in the serum calcium level, and the improvement noted electroencephalographically

Robinson et al (1954) suggest that the basic electrical rhythm is responsible for the abnormal pattern in the electroencephalogram, but this case supports the hypothesis that the changes are largely due to a biochemical abnormality

The appearance of the teeth indicates retarded development due to some factor supervening about the age of 8 years The epilepsy in this case also began at 8 years, and one can assume the onset of hypoparathyroidism near that age This dental finding fully agrees with the suggestions of Albright and Strock (1933)

Calciferol was as efficacious as dihydrotachysterol in bringing the serum calcium and serum phosphorus levels back to normal and was less expensive The serum phosphorus level was very high again in February, 1955, although the serum-calcium level was normal. this indicates a renal tubular defect with increased resorption of phosphorus

Summary

A case of idiopathic hypoparathyroidism presenting with epilepsy from the age of 8 years and recently developing megaloblastic anæmia is described

The probable cause of the anæmia is discussed

I wish to thank Dr H Hilton Stewart for permission to report this case, which was under his care, and for his advice

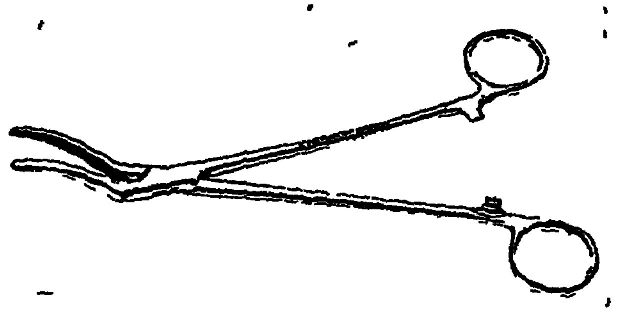
New Inventions

PULMONARY-HILUM CLAMP

The clamp illustrated here was devised about two years ago for use in the thoracic unit in Manchester and has been used by several surgeons in many pulmonary resections

There are occasions when, owing to inflammation or to neoplastic enlargement of glands, the distal ends of the pulmonary vessels are difficult to secure satisfactorily either by ligature or by the commoner clamps—e g, straight Spencer Wells, Roberts forceps, and cholecystectomy forceps



Sometimes a Roberts or a cholecystectomy forceps could be applied backwards to the distal ends of the vessels, or alternatively the vessels could be cut distally and allowed to "bleed back" In such a situation a fairly strong clamp with an angled shank and a reversed curve on its blades, which are longitudinally serrated but no wider than a Roberts forceps, gives most satisfactory control without fear of slipping This instrument has a strong box-joint so that it can also be used, if necessary, as a distal clamp on the bronchus without straining it

I am indebted to Mr H Woodall, of Allen & Hanburys, for having the clamp made to my specifications All inquiries should be addressed to him

express my opinion that his point of view is superficial, irresponsible, rather superior, and lacking in perception

Beckley, Rye, Sussex C G LEAROYD

SIR,—Dr Comfort attributes the legal attitude to homosexuality largely to emotion, but is it not due to the legal respect for custom? The reasons for custom may or may not be apparent, or valid Incest is taboo presumably because of a "tribal" fear of procreating poor stock On this premise, if the fear is groundless logical argument against incest fails Incest between consenting adults becomes no more culpable than other varieties of sexual relationship between consenting adults

I feel sure, however, that the "tribe" would maintain its taboo on incest without logical explanation Likewise it will maintain its taboo on homosexuality between consenting adult males, which may well have social consequences that are not obvious (Even so, the feminising effect on the passive partner of such relationships seems an obvious social evil)

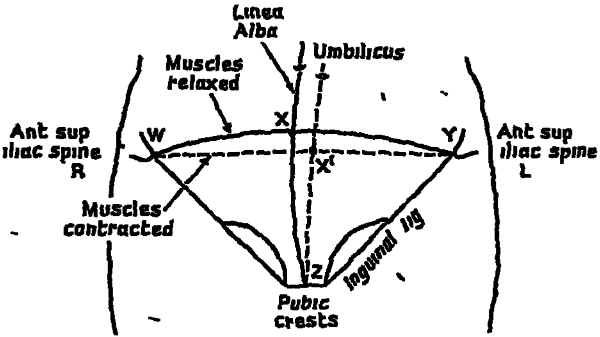
Penalties may be savage and defeat their object, but let us respect the wisdom of our forefathers

Barton on-Humber, Lincs S H F HOWARD

INGUINAL HERNIORRHAPHY

SIR,—I agree with Dr Robinson (Jan 7) that the "fixed point" has meaning only in the coronal plane

In the sagittal plane, as the accompanying figure shows, it moves in the way he describes, moreover, it shows the representation of the points as a pyramid I agree, also, that as the apex of the pyramid, X, moves anteriorly there is a tendency for the gap between the conjoined tendon and inguinal ligament to increase The radiographs referred to by Dr Robinson provide no information on this point The first film was taken with the abdominal musculature relaxed "normally", the second film was taken with the abdominal wall drawn *backwards* by strong contraction No change was detected in the distance between the markers No film was taken with the abdomen "blown out", if one had been taken, an increase in the gap between the markers might have been seen, because the usual clinical method of "bringing down" a small hernia is to make the patient "blow out" the abdomen with a cough



Lastly, I must ask Dr Robinson how the conjoined tendon can contribute to the integrity of the inguinal canal except by literally acting as a "shutter" in the way described by Keith

Mr Forty (Jan 7) asks for the number of recurrences in the group of patients whose "markers" have separated The answer is none at present I agree that if the conjoined tendon is pulled off the inguinal ligament a sheet of fibrous tissue probably bridges the gap If the declared object of sewing the conjoined tendon to the inguinal ligament was to create this fibrous sheet no protest would be necessary, provided it succeeded, but as this intention is not usually understood with this operation, it would appear that the surgeon "succeeds" owing to an accidental event, and is robbed of his satisfaction thereby

With regard to the suture material in some cases catgut was used, in others silk No nylon was employed The relative merit of catgut and silk are being tested in another investigation, which will mature this year, of 100 cases followed up for two years

WERTHEIM'S HYSTERECTOMY

SIR,—I feel that I must reply to certain points raised by Mr Mills (Jan 14) He refers to the "comparative unpopularity" of the synchronous combined abdomino-vaginal hysterectomy I do not think that his phraseology is quite fair as my colleagues and I have performed over fifty of these operations at St Bartholomew's and other hospitals, and many gynæcological surgeons, both foreign and British, who have come to watch the operation have been impressed with its possibilities

Mr Mills is correct in saying that the operation requires an expert theatre staff and team of assistants, and I have been fortunate in having a series of first-class registrars all of whom have shown themselves most competent operators In my original article I stressed that this operation should only be done in a large and fully equipped department, and my experience with the operation has amply confirmed this

The great advantage of the synchronous combined operation is that the two surgeons, working together, can completely remove the parametrium and paracolpos without changing the position of the patient, and although I commend Mr Mills's idea of an asynchronous combined operation, I do strongly recommend him to try the operation as I described it,[1] when he will appreciate the superiority of the combined technique Apart from providing a wider dissection, the operation is easier and quicker to perform, and he will find the help of his nether colleague of inestimable value when dissecting the bladder from the parametrium and vagina

I would raise, however, one criticism If Mr Mills starts his operation from below and thereby commits himself, he may well find on opening the abdomen that it is not feasible to complete the operation—for instance, if malignant glands are irremovably fixed to the external iliac artery or if the aortic glands are involved Both these complications have occurred in my experience and deterred me from further surgical treatment Our practice now is to open the abdomen with the patient in the St Mark's Hospital position, using the Lloyd Davies

view, but in fact supports my own contention, the extreme sensitivity of tocopherols to various physicochemical processes, with consequent loss of biological activity, was demonstrated at the third International Congress on Vitamin E by several speakers in September last

Apart from this divergence of opinion, I endorse wholeheartedly the authors' view that the serum-cholesterol level is not the only, let alone the decisive, factor in the incidence of coronary heart-disease There can be little doubt that the whole blood "chemo cosmos," so to speak, conditioned by the total food intake and the various digestive enzymes, among other factors, has an important rôle

London W 1 L SCHMIDT

Parliament

Guillebaud Report

IN announcing the publication of this report on Jan 25, Mr TURTON, the Minister of Health, said that its main conclusion was that it would be premature at this point to make any fundamental alteration in the structure of the National Health Service In the committee's view what was most needed at present was the prospect of a period of stability so that the authorities and representative bodies could think and plan ahead with the knowledge that they would be building on firm foundations The committee specifically indicated their support, by and large, of the main administrative features of the services, including, for example, the present method of making Exchequer money available for the hospital service With the committee's general conclusion and approach on these matters the Government were in agreement

The committee pointed out that the aim must be to provide the best service possible within the limits of the available resources, and that it must be for the Government to determine as a matter of policy how much of the national resources, in terms of finance, man-power, and materials, could be made available for the health service, regard being had to the competing claims of other social services and national commitments

The committee's recommendations on organisation and management of the service included a recommendation on the desirable rate of capital expenditure in the hospital service The Government decided some time ago that the present level of expenditure should be increased in the years up to 1957–58 The committee proposed that, after that, if the resources could then be made available, £30 million annually would be a desirable level at which to aim over the seven succeeding years

The committee further recommended that when financial circumstances permitted, the existing Exchequer grant towards the capital cost of providing residential accommodation for the aged should be replaced by a 50% grant on the net total expenditure of local authorities on such accommodation This proposal would involve legislation and would also require consideration in the wider context of the relation of local-government finance with the Exchequer There were a number of recommendations either for continuation or for development of measures already in hand or contemplated or for detailed adjustments in the present arrangements These recommendations would require careful consideration He must, moreover, make it clear that in view of the economic situation the Government could not undertake any additional financial commitments in respect of the health services at present

The committee's final comment included a tribute to the service's record of performance and a finding that any charge of widespread extravagance had not been borne out by the evidence

Mr ARTHUR WOODBURN asked whether the Government were bearing in mind that real economy would come when the hospitals could be made more efficient by new capital expenditure A great deal of waste arose from the use of old buildings and appliances and the difficulties experienced by doctors and nurses in carrying on their work He hoped that the Government would realise that cutting down cap expenditure was not necessarily the way to secure econ and that it might be better to spend a little more mon now in order to save over the years In examining the rep he hoped that the Minister would not close his mind t further expenditure if that was necessary to restore an people to work Mr TURTON The Government apprecia those points That is why in the programme for 1956-5 and for 1957–58 there is provision for plant replacem Dr BARNETT STROSS May we interpret what the Minister h said as meaning that as soon as there is an acknowledg improvement in the economic situation of our country th essential recommendations in this valuable report will b given the highest priority? Mr TURTON First we mu study this report and I must have consultations with th local health authorities on many of its detailed recommenda tions Until that has been done it would be wrong for me t make any commitment

QUESTION TIME

Ban on Heroin

Replying to questions, Major GWILYM LLOYD GEORGE, th Home Secretary, said the Government's aim in deciding t ban the manufacture of heroin was to coöperate in a wid spread international effort, to which more than 50 countri had subscribed, to help to eliminate the abuse of the drug i various parts of the world Before reaching the decision th Government had taken the advice of the statutory advisor bodies, namely the standing medical advisory committees i England and Wales and in Scotland The Government ha however, been advised that it was not possible under th present law of this country to prohibit the manufacture heroin There was no similar legal obstacle in the way prohibiting the export and import of heroin, and the Gover ment had accordingly decided to prohibit entirely as fro Jan 1 exports of this drug to countries outside the Briti Islands, except for such small amounts as might be necessa for scientific purposes only, and all imports The Governme had decided to restrict the manufacture of heroin in th country to the quantities actually required for home medi consumption and scientific use

Mr HUGH GAITSKELL Is this a permanent decision abo manufacture? Was not a statement made by the Governme that they proposed to allow manufacture, though not expo for twelve months? Does this latest decision mean th manufacture is to be permanently permitted?—Major LLOY GEORGE The term of the licence is for twelve months in eve instance, although there is a clause which enables it to cut short Twelve months is the normal period of the licen The Government will not at present go beyond this per as the licence itself is valid for twelve months We are touch with the Medical Research Council to ascertain feasibility of developing the other substitutes

THE LANCET

LONDON SATURDAY, FEB 4, 1956

Guillebaud

WHETHER it pays publicly or privately, no nation can hope to have anything like a first-rate modern medical service without spending a great deal of money. Unfortunately the original estimates for the National Health Service were too low; and when, with prices rising, its cost seemed to be higher each year, the increase was widely attributed either to wastefulness or to unreasonable development. Alarmed lest this expenditure should get out of control, the Government in May, 1953, appointed the Guillebaud Committee, with ominous terms of reference: it was to advise how a rising charge on the Exchequer could be avoided while maintaining an "adequate" service, and to suggest means of ensuring "the most effective control and efficient use of such Exchequer funds as may be made available." Faced with these questions, such a committee might easily have sought quick and ruthless answers based on a superficial examination of the facts; but happily this was not the way of Mr GUILLEBAUD and his colleagues. Their eagerness to question and their readiness to listen have been exemplary; and the results of their methodical weighing of evidence are seen in the report now published, which takes up most of the controversial issues in the service, sets out the arguments on both sides, and concludes modestly with "our own view." Even if they had done nothing more, and made no constructive proposals, we could be grateful to them for providing, on so many subjects, the convenient starting-point for all further discussion.

But they have done much more. The review of N.H.S. expenditure made on their behalf by Prof. R. M. TITMUSS and Mr BRIAN ABEL-SMITH, PH.D., and described by the latter in our last issue, shows that costs, as realistically defined, have not in fact been soaring. Nobody would deny that, for various reasons, our medical services now employ far more people than they did before the war or even in 1947; but in terms of 1948–49 prices the net cost of the N.H.S. to public funds continued its initial rise only till 1950–51, and in the next two years it returned to approximately its level in its first full year (1949–50). In 1953–54 it was again a little higher; but, allowing for changes in the age structure of the population, the net cost per head at constant prices was still almost exactly the same as in 1949–50 (£8 15s. as against £8 12s.). During these years the national income rose, and the proportion of the gross national product used by the N.H.S. fell steadily from 3.80% in 1949–50 to 3.42% in 1953–54. "It may come as a surprise to many," the committee truly remark, "to find that the National Health Service has absorbed a decreasing proportion of the country's resources since the year 1949–50." Similarly, the proportion of national investment devoted to the N.H.S. has never reached 1%; and by 1953–54 it was down to 0.53%. In real terms capital expenditure on hospitals has averaged about a third of what it was before the war; and (though these figures are not strictly comparable) the ratio of capital to current expenditure on hospitals in England and Wales fell from 19.6% in 1938–39 to 4.1% in 1952–53—the corresponding figure in the U.S.A. in 1951 being 23.4%. The committee recommend that if possible £30 million a year should be found for the capital needs of the N.H.S. in the seven years after 1957–58 (how much will that be worth then?), and they emphasise the need to look after the buildings we have. Any suggestion that a low rate of capital expenditure has been suitable because the hospitals were in good condition on the appointed day can be rapidly dismissed. TITMUSS and ABEL-SMITH estimate that in England and Wales 45% were originally erected before 1891 and 21% before 1861. Though the running cost of the hospitals has increased progressively since the N.H.S. started, being nearly £30 million higher at 1948–49 prices, in 1953–54 than in 1948–49, they do more (and often better) work for a larger population. In the committee's view:

> "... the experience of the last seven years does not suggest that the organisation has failed to cope with its heavy responsibilities or to control with greater regard for economy than is commonly credited, the large sums of Exchequer money which have been devoted annually to the Health Service. As we have already pointed out, the annual capital allocations for the hospital service have, in our view, been inadequate, but there can be no doubt that the hospital authorities have made very good use of the limited sums made available to them. Any charge that there is widespread extravagance in the National Health Service, whether in respect of the spending of money or the use of manpower, is not borne out by our evidence."

For those of us who did not need this reassurance there is more interest, however, in the Guillebaud Committee's observations on the weaknesses of the service, on which they say:

> "It certainly should not be concluded that we have found the present organisation and administration of the National Health Service to be free from defects. In particular there is much need to integrate more closely the hospital, family practitioner and local health services, and also the welfare services provided by local authorities under the National Assistance Act. We also believe that the hospital service has been somewhat slow to adopt certain methods and techniques of management which have proved their worth in other large-scale undertakings, for example, in making adequate provision for the maintenance of capital assets, making full use of budgetary controls, devising the most economical means of purchasing supplies, making provision for a national recruitment and training scheme on the administrative side of the service, &c."

As may be gathered from this analysis, the remedies they propose are changes in practice rather than in principle. When they were first appointed they were told by witnesses that health could be restored to the service only by loosening controls—the control of the Treasury over the Ministries, of the Ministries over the regional boards, and of the boards over the management committees. At all levels, it was said, good work could be expected only if people were given responsibility for spending their own money and making their own mistakes. But not even for the sake of an entirely novel service are the committee prepared to recommend a change of Parliamentary practice that would give a Ministry, a board, or a committee money which would be theirs to keep if they did not spend it all. Correctly enough, they point out that all that Parliament gives is permission to spend up to a certain sum in a certain period, and they reject pleas both for block grants and for carrying over balances. On the other hand, in dismissing

Annotations

PRINTING OF THE LANCET

THIS issue of our journal has been truncated at a late stage in its development, and we have reluctantly had to omit many letters and other contributions intended for immediate publication At the time of going to press we do not know what developments are likely in the present dispute in the printing trade We can do no more than assure readers, contributors, and advertisers that we shall try to produce each week at least a token issue, and if this cannot be printed in more than token numbers we shall send copies later to all subscribers Publication of normal issues will of course be resumed as soon as possible

INTRACRANIAL BRUITS

AUSCULTATION of the skull is often omitted from a neurological examination, but Mackenzie,[1] in a recent account of intracranial bruits, has drawn attention to the importance of this method of examination Travers,[2] in 1809–11, appears to have been the first to record an intracranial bruit, in a patient who in all probability had a carotico-cavernous fistula, and some years later Fisher[3,4] made a number of observations on the "cephalic bellows sound" He found this sign in children with chronic hydrocephalus and congestion, acute inflammation, and compression of the brain, and he thought the bruit resulted from impediment to the free passage of blood through the basal arteries as they were compressed by the diseased brain against the bony channels in which they ran In 1843 Whitney[5] noted a bruit in an adult with an aneurysm of the basilar artery, and in 1898 Hoffman[6] made the first presumptive diagnosis of an intracranial angioma when he heard an intracranial bruit in a patient with a spastic left hemiparesis

An intracranial bruit may be hard to hear, and it should be listened for in quiet surroundings, which are often difficult to find in an outpatient department It is often heard best over one or other eyeball, but auscultation should also be carried out over the temporal fossæ and the mastoid processes The condition most commonly associated with an intracranial bruit (sometimes a very loud one) is a carotico-cavernous fistula, usually the result of trauma but sometimes due to spontaneous rupture of a carotid aneurysm into the cavernous sinus A bruit can be heard in some intracranial angiomas, and it is perhaps in this condition that careful auscultation of the head is of most value The proportion of these patients in whom a bruit has been heard varies in different series Tonnis[7] recorded it in only 4 out of 22 patients, but Mackenzie,[8] in a previous study of 48 patients with intracranial angiomas proved by arteriography, recorded a bruit in 24 He made the interesting observation that a bruit was heard in 65% of the patients in whom the presenting symptoms were epilepsy, periodic headaches, or a hemiparesis while it was uncommon in patients whose initial symptoms were a subarachnoid or intracranial hæmorrhage The importance of listening for a bruit is emphasised by 2 case-records given by Mackenzie A patient aged 23 had had minor epileptic attacks for seven years and 2 major attacks in the fifteen months before she was seen at hospital, the only focal feature about the attacks being a transient aphasia at the onset a bruit heard over the left eyeball indicated carotid angiography and this showed an angioma in and around the left Sylvian fissure Another patient had begun to have attacks of migraine at the age of 12 the visual aura was always on the right and the headache on the left At the age of 26 she had a persistent defect in the right lower quadrant of the visual field At 41 a bruit was heard over the left eyeball and left mastoid process, and arteriography showed a large left occipital angioma

Mackenzie records the rare occurrence of a bruit with a non-communicating intracranial aneurysm, a frontal meningioma and a glomus-jugulare tumour, and for a short time in a patient with occlusion of the internal carotid artery The occasional presence of a bruit in children with raised intracranial pressure is well recognised, and Mackenzie mentions 2 cases of this kind, in 1 the pressure was raised by a pineal tumour and in the other by cerebral thrombophlebitis He emphasises that an intracranial bruit may at times be heard without any other indication of an intracranial lesion, and that the presence of a bruit does not in itself warrant further investigation He refers to a patient in whom a bruit apparently due to a moderately severe anæmia disappeared when the anæmia was corrected Another unpublished observation is in keeping with this, a physician who had had two large gastro intestinal hæmorrhages heard a noise in his left ear which was synchronous with the pulse and which stopped completely on carotid compression, the noise disappeared when the anæmia was corrected by blood-transfusion Although it is not known whether this noise could be heard by an outside observer the patient described it as having the characteristics of an intracranial bruit, a sound with which he was familiar.

The site of origin of an intracranial bruit is usually considered to be the arteriovenous communication which occurs in carotico cavernous aneurysms and many intracranial angiomas but Mackenzie suggests that another mechanism may be important in some cases With intracranial vascular abnormalities there may be increased blood flow through the carotid or vertebral arteries, and he suggests that, particularly in the carotid, there may be a relative stenosis where the artery enters the intracranial cavity This may be the origin of the bruit, and it would explain why it may be heard most easily over the eyeball A similar mechanism of relative stenosis of the basal arteries would explain the bruit in children with raised intracranial pressure—the explanation originally suggested by Fisher in 1838

ACUTE HÆMORRHAGIC LEUCOENCEPHALITIS

ALTHOUGH Wernicke's disease and brain purpura[1] were early differentiated from the many cases of hæmorrhagic encephalitis described during the past eighty years, it is only comparatively recently that further subdivision has been possible Necrotising hæmorrhagic encephalitis[2] and acute hæmorrhagic leucoencephalitis[3] are now usually recognised as distinct entities, although Adams and Kublik[4] maintain that they are a single disease All 16 recorded cases of acute hæmorrhagic leucoencephalitis show a similar pathological picture characterised by severe vascular damage, with fibrin impregnation of the walls of venules, capillary disruption, multiple hæmorrhages of ring and ball types, perivascular necrosis, pronounced leucocytic infiltration, widespread focal and perivascular demyelination, and a microglial reaction

A lead to the understanding of the ætiology of hæmorrhagic leucoencephalitis was given by Russell[5] when she pointed out its similarity to acute disseminated encephalomyelitis and produced evidence suggesting an allergic basis for both conditions Lander[6] records the case of a 36-year old man who had hæmorrhagic varicella ; on the fifth day of the disease he lapsed into coma and he died four days later Necropsy revealed the typical features of

entertain today about this complicated and fascinating problem The man on the bridge between basic research and clinical practice whom I select for this purpose must inevitably bear a certain resemblance to myself, his views will therefore be not a little confused by the fact that I am normally to be found as busily engaged in the direct clinical application of a specialised technique as most of the others on one side of his bridge and at least as biased and full of foibles as the rest This pontine figure of my imagination should look impartially and hopefully to either side, but since his own state of mind is necessarily temporary and subject to change, and since, though most parts of it may be sympathetically regarded from one side or the other, the whole is likely to appear curiously misshapen from both, he should not always expect such tolerance in return It is important that he should have a flexible, sensible, and general view against which he can test the claims that are made and into which he may either fit new knowledge or use it to change his outlook For the rest of my address I shall be attempting to see the cancer problem and some of the people engaged on it as they might appear today from this precarious viewpoint

To my selected middle man, cancer is a human disease process which has only been defined in terms of behaviour He knows that each doctor decides for himself what number and what degree of several abnormal behaviour patterns he will accept in each particular patient before he attaches the diagnosis He sees the mistakes that are made from time to time in this assessment, to the pride and profit of quacks on the one hand, and to the dismay and frustration of clinicians on the other He recognises that growth may be excessive or invasive, or even perhaps metastasising, and still be benign, that a tumour may be a malformation or a neoplasm or neither or both, that the degree of malignancy of undoubted cancers may so vary that one may be far more easily curable than many other diseases and another so catastrophic that the patient disintegrates before our eyes A tumour may progress through every borderline stage in each one of its behaviour characteristics after another and, if hormone dependent or conditional, may still retain this property long after dissemination has occurred or lose it at any time during this progression The process may start in many cells at about the same time in one localised area, in one organ, or in scattered homologous tissue in different parts of the body The distribution of cancer throughout the animal kingdom, the rather similar changes which take place in plants, and the involvement at times of almost every tissue in the human body, suggests to him strongly that this behaviour pattern must be something fundamental biologically The different factors which incite and promote this change in behaviour, the long latent periods which occur, the widely different degrees of growth potential revealed, and the similarity of average age at diagnosis despite a widely different incidence in those exposed and those not exposed to some carcinogenic agents, all seem to favour a balance between growth and growth restraint which weakens sharply with advancing years The fact that so many different stimuli—both internal and external to the cell—can provoke this change in behaviour and that they are not always, or even usually, necessary for its continuance, seems to indicate that the capacity for unlimited growth which is expressed must reside within the cell itself

To him, however, it is an assumption to conclude that this capacity must therefore be unusual, peculiar to the cancer cell, or necessarily due to some special, specific change within it There seems to be little evidence that chemical or structural changes have yet been found in cancer cells which are not present in normal cells in different stages of embryological development and differentiation Unlimited growth potential holds for unicellular organisms, it has to be shown that it does not do so for the multicellular A fragment of chick embryo, doubling its original size every forty-eight hours, has, we are told, been growing in culture for nearly as many years The fundamental behaviour pattern which expresses a capacity for unlimited self reproduction seems no less than life itself There does not appear to be any obvious reason, beyond man's wish to find it, why there should be some special growth potential within the cancer cell thought to be evil which is any different from or any more or less mysterious than that already existing in all living things and thought to be good He suspects the introduction of a value judgment into an exercise devoted to the understanding of a phenomenon of Nature

The emergence of new qualities from increasing complexity of structure is another fundamental biological property which seems to him to be relevant New qualities not present in the various parts which go to make some new whole nevertheless arise from their combination The nuclear physicist's world of fundamental particles is free of quality, while the sphere of the biologist is packed full of them in glorious and confusing abundance An electron is not hard or red or beautiful but, with other particles equally lacking in these qualities, goes to make structures which may appear to be all three Similarly the adding together of cells in a pattern to make an organism produces new qualities which are not inherent in the cells themselves One of the most necessary qualities for survival which must arise is organisation As evolution, by producing increasing complexity, has allowed the development of more and more qualities, so it has demanded and selected better and better organisation

Each cell in the human body, being produced by mitosis as a direct descendant of the original fertilised ovum, carries within it all the inherited potentialities to which the individual is heir These cells do not remain alike, however, most of them by differentiation become type specific, giving up some of their inherited potentialities for expression in growth and form while acquiring specialisation in function

The processes of asexual reproduction, of regeneration and wound healing, and of neoplasia have much in common Some dedifferentiation followed by cell immigration and an increase in mitosis are usual Dedifferentiation is a necessary preliminary to regeneration and, even in tissue-culture, cells normally dedifferentiate to some extent before they begin to divide With controlled regeneration, mitotic-rate and degree of differentiation are inversely related—that is, mitotic rate decreases as differentiation increases—the process being organised, with tumour formation, mitosis is directly related to the degree of dedifferentiation first achieved, but it tends to be maintained at this rate since differentiation fails to return again, the process being disorganised

It is this failure of organisation which appears to be the fundamental factor in neoplasia, distinguishing it from agamic reproduction and regeneration Multifocal origin, variation in degree of change in several behaviour characteristics, progression in those changes, and conditional growth, all seem to be more easily understandable in terms of progressive relaxation of different controls and of cell reversion by varying steps of dedifferentiation to the reassertion of an inherent independence and individuality The multiplicity of causes of relaxation of control and the continuance of the new behaviour pattern, even when inciting factors have ceased to operate, also seem easier to accept on this basis To this middle man, any special intracellular evil, be it mutation, virus, special disorder of nucleic acid metabolism, or any other unnatural agent which increases cellular activity or damages its controlling that multiplication of the souring organisms will check the increase of staphylococci either by competition for nourishment or by the production of some inhibitory substance, such as nisin Perhaps raw milk contains sufficient staphylococcal enterotoxin to produce symptoms only when by some uncommon chance the staphylococci have had a flying start in the multiplication race

Whatever the theoretical dangers, common experience suggests that the milk, raw or pasteurised, which passes through the normal channels of commerce is almost free from risk For this reason eight large outbreaks of food poisoning within a month, all due beyond doubt to reconstituted spray dried milk supplied to its schools by one local authority, gave rise to some alarm [2] While no pathogenic bacteria could be isolated from any of the victims of these accidents, *Staph aureus* (phage-type 42E/53W) was found in all the suspected batches of milk-powder, which were all from one maker Serial examination of the daily batches from this factory showed staphylococci in almost every sample in numbers which varied widely from day to day but which seemed to reach a maximum in the early summer Spray dried milk-powder from other makers showed, with one exception, far lower figures throughout the year Roller dried milk showed no staphylococci at all Since, however, the milk which caused gastro enteritis was drunk within four hours of being reconstituted (a time too short for bacterial multiplication), it was clear that the staphylococci in the powder were by themselves insufficient to account for the effects produced The powder must have contained a large amount of enterotoxin, probably produced at some stage in manufacture and surviving the process of drying

The spray-drying of milk consists essentially of pasteurisation, evaporation to about one third of the original volume, and drying by injection of a fine spray into a current of air at 320°F The raw milk before processing contained many staphylococci, but because it was kept chilled at 40°F it was unlikely to be the source of enterotoxin Laboratory tests confirmed the expectation that few bacteria survived pasteurisation and evaporation Between this stage and drying, it is customary to run the milk through a balance tank which eliminates fluctuations in the flow to the drier At the beginning of the working day, the bacterial content of the milk in this tank was negligible, but within a few hours it rose as high as 100 million organisms per g, and staphylococci were almost invariably present Drying reduced the numbers of bacteria but did not kill them all Since staphylococcal enterotoxin will withstand boiling for several minutes its potency was probably little altered by this last stage in the process

The balance tank in such a plant offers unusual opportunities for bacterial multiplication The evaporated milk is warm It tends to deposit a sludge which can be removed only at the end of the day and which offers excellent pabulum to bacteria as well as slowing the flow through the tank It is less clear how it becomes infected It may be by aerial contamination More probably some sin of omission in the daily cleaning or the working of the pasteuriser allows the entry of a few staphylococci which can then multiply indefinitely It may or may not be important that staphylococci were most abundant in the milk dried in early summer, which is the time when the largest volume of liquid milk reaches the factories and when, in consequence, the drying plant works a longer stint than usual The longer the run, the greater the likelihood of bacterial multiplication to dangerous levels in the balance tank

It would be unwise to make too much of the risks revealed by these accurate and elegant investigations Many hundreds of gallons of reconstituted spray-dried milk are given to children, and the recorded accidents are less than a dozen The practical measures to prevent such accidents in the future must remain the responsibility of those who dry the milk It is probable that small changes in design or operation will do all that is necessary The detection of staphylococcal enterotoxin is impracticable as a routine measure, and we must rely substantially on the good sense of the manufacturers

ŒSOPHAGITIS

ŒSOPHAGITIS has aroused interest because of its association with hiatus hernia, and the two conditions have become so closely linked in our minds that we may be misled into believing that œsophagitis is always associated with gastric hernia, and Lodge [1] has shown this is not so There is the question of cart and horse, for œsophagitis, leading to shortening of the œsophagus, can draw the stomach up into the thorax, and it may be hard to decide in a late case whether hernia preceded œsophagitis or vice versa Peters [2] has studied 116 cases of œsophagitis selected from 20,000 necropsies, slight and doubtful lesions and those not due to peptic digestion were excluded After analysing the clinical and pathological records, he found that, though the causes were often multiple, in 66 3% the trouble was largely due to factors outside the cardia or hiatus which upset the mechanism responsible for closure of the cardia Repeated vomiting (from pyloric stenosis or pregnancy, for example) and increased intra abdominal pressure (from such causes as obesity, ascites, and pregnancy[3]) may be the start of persistent inflammation Acquired hiatus hernia and congenital enlargement of the hiatus accounted for another 20 3% of cases These observations are important surgically since they emphasise that correction of the hiatus hernia will not necessarily relieve an associated œsophagitis

From the Mayo Clinic, Schmidt [4] gives warning against operations involving the cardia, such as œsophago gastrostomy for cardiospasm or stricture, or a similar anastomosis following excision of a lower œsophageal growth, for œsophageal ulceration ensues in a high proportion of cases Experience at the Lahey Clinic [5] has also shown that resection of the lower œsophagus and cardia for chronic œsophageal stricture, or for megaœsophagus, is disappointing because of subsequent recurrent ulceration, an associated operation to drain the stomach, such as pyloroplasty or gastrojejunostomy has been advised Nevertheless, Neuman and Ellis [6] have shown experimentally that these operations do not reduce the incidence of œsophagitis after œsophagogastrostomy in dogs, and that the condition can be controlled only when the acid-bearing area of the stomach is removed by pylorectomy Thus, Wells and Johnston [3] recognising the failures after repair of hiatus hernia undertaken to relieve symptoms of associated œsophagitis, have performed partial gastrectomy not only to ensure drainage away from an incompetent cardia but also to reduce gastric secretion This procedure defeated its ends in 2 of their patients, for œsophagitis persisted because of the regurgitation of bile, and they now also divert the duodenal secretions with a Roux-en Y anastomosis Whether this technique will introduce further complications, such as anastomotic or jejunal ulceration (as the vagus nerves are also divided, this may be avoided) or steatorrhœa, remains to be seen, Wells and Johnston have met no such difficulties in 12 patients treated so far Their method seems to be a reasonable surgical answer to the otherwise intractable problems of œsophagitis without hiatus hernia and the shortened œsophagus which prevents the reduction of a hiatus hernia

confident They are well aware of the importance of asking the right questions if they are to expect reasonable answers, and in their own fields are unlikely to be caught in this old trap for long In the wider, unfamiliar sphere of cancer to which they bring their special knowledge and skills, however, they too often appear to accept the basic questions put without the same critical inquiry It may be that the worthy, emotional, but unscientific appeal of becoming a public benefactor, or at least of sharing in such benefaction, attracted some of them from the start, so that they entered on their work with an element of prejudgment on questions of discoverable cause and cure which prevented them at the start from stopping to examine these fundamental propositions too closely They are entitled to study whatever aspect of the subject they may choose to follow—this is the privilege of their calling—but much of what they study does not seem to bear much resemblance to what we hoped they had set out to study There are many of them who have become so fundamental that they appear to be looking for a cause of something which seems to be life and for a cure of something which seems to be the second law of thermodynamics

The vast effort which he sees on this side of him is, under the guise of cancer research, mostly directed towards unravelling the basic mysteries of life and living It could hardly have a more worthy object, it demands our increased support That so much basic biological work should be financed through its cancer relationship may possibly be a mistake, however, since this may have tied it too closely to the demand for an answer to a specific problem which has not even been properly set Cancer research achievements have been great, they are only underrated because they have supplied no simple solutions to the questions of cause and cure of the disease process to which they are officially dedicated Judged, as they should be, on their own merits, they are seen to have made important contributions to an immense range of scientific inquiry which is in itself a fascinating story The twin compulsions of an emotional desire to rid mankind of a killing disease and the constant demand for answers from those who provide the money do seem, however, to have had some ill effect on cancer research A few workers have rashly abandoned their privileged seclusion at times to announce in public that they are on the trail and that a capture may shortly be expected The almost hysterical note to be heard in some demands for cancer-research expansion, carrying an implied threat that if they are not met the public cannot expect the solution in a reasonable time, has not always been confined to the administrators This unhealthy and unscientific atmosphere for the quiet pursuit of fundamental knowledge may not be widespread but there is enough of it to be clearly seen The middle-man may well feel that another look at the proposition that there is no single simple solution, no specific intracellular evil, and no universal cure for them to discover might blow this mist away What he wants from these research workers is knowledge about the fundamentals of life and living, of biological organisation and disorganisation, and an understanding of growth, development, and decay They may take their time, they have all the time there is Each new discovery is a welcome gain in knowledge They should be content with this, their proper heritage in cancer research as in other fields, the responsibility for the application of their work is not really theirs If they feel an obligation to produce results which both please the public and advance the cause of science, the middle man wonders why they do not more often help to put a few extra people on his bridge

Clinical Cancer Work

To the other side of the bridge as he looks towards the clinical cancer workers, he sees quite another scene Here is no group diverse in training and devoted to a single aim, but the whole of medicine Doctors with much the same basic training in fact but of whom few are primarily engaged in cancer work though most of them have regular and direct contact with it It is perhaps surprising how few doctors are deeply and daily concerned with a large range of cancer patients Those surgeon whose interests have centred on one part of the body, and who have acquired by long experience special skill in dealing with malignant disease at this site, are primarily concerned with the advance of their specialty and have not often paid much attention to more general cancer problems This trend has been of the greatest value in diagnosis, in studying the natural history of the disease, and in local treatment, but, as a result, it has been left to comparatively few surgeons to take an active interest in the whole wide field

The situation is temporarily rather different for the radiotherapists They see more patients with a far greater variety of tumours than any of their colleagues, and a bigger proportion of those they see have advanced disease Specialisation is now developing within the larger radiotherapy departments, for the very same good reasons which led to specialisation in surgery in the past Cooperation in special clinics between surgeons and radiotherapists with similar interests has greatly improved the quality of the treatment given but emphasises still further the need for clinicians with a wider research interest in this whole process of disordered growth

Our middle man recognises that it does not seem very important to some people that physicians and surgeons concerned with cancer should have any very profound knowledge of this disease process The steady fall in the incidence of mouth cancer which has followed better dental care and a decline in pipe smoking, the dramatic change in diagnosis of lung cancer and the improvement in results of treatment of testicular tumours, are random examples of advances which have not been dependent on any very fundamental understanding of growth and organisation Nevertheless he feels that a change of outlook on this great medical and social problem by doctors might have important consequences

One thousand eight hundred years ago Galen classified tumours as being according to nature, exceeding nature, and contrary to nature, and a better division of this fluctuation in growth and control, if nature in this context means organisation, has not since been made One hundred and eighty years ago Percivall Pott described occupational cancer, carcinogenesis, the curability of localised tumours, the importance of factors outside the tumour, and the disappointments of palliative treatment He wrote

> "The disease, in these people, seems to derive its origin from a lodgment of soot in the rugæ of the scrotum, and at first not to be a disease of the habit In other cases of a cancerous nature, in which the habit is too frequently concerned, we have not often so fair a prospect of success by the removal of the distempered part, and are obliged to be content with means, which I wish I could say were truly palliative"

Although the carcinogenic hydrocarbons have since been discovered and an immense amount of work has been done on relative potencies of tumour inciting and promoting agents, there have only recently been signs of a real advance in understanding The simple view that the whole trouble lies in a specific evil within the cell resulting in its autonomy, which has become so widespread, threw the emphasis away from medicine and on to the chemist and the cytologist The result has been that ideas no longer flow as easily as they should from clinical to basic research interests Too many research workers feel that the clinician has nothing more of interest to say since he knows little of intracellular mechanisms, and too many clinicians feel that

Prior Approval of Expenditure.—At present regional boards and boards of governors have to seek approval from the Health Departments for capital works costing more than £10,000, and the Health Departments approval from the Treasury for capital works costing more than £30,000. These limits should be raised to £50,000 and £100,000 respectively.

Appointment of Staff and Establishments.—The existing controls over the appointment of consultants and junior hospital medical staff in England and Wales should be retained, but the controls over other categories of staffing establishments should be relaxed as far and as fast as possible. The hospital authorities should themselves regularly review their establishments. There were reasons why in the early years the Ministry should send out its own establishment review teams; but henceforth, responsibility for ensuring economy in the use of hospital staff should remain fairly and squarely with the regional hospital boards and boards of governors—with the proviso that the Boards must seek the authority of the Ministry for any additional consultant appointments.

Medical Consultation at Regional Level

The committee have little doubt that the medical profession would welcome the appointment of statutory medical advisory councils in all regions; but they see objections. Taking these together there is sufficient weight in them to deter the committee from recommending the establishment of statutory medical advisory councils for all regional hospital boards. But they urge all boards to review their arrangements for joint consultation with the medical profession, and to consider whether medical consultative committees could with advantage be set up at regional level to ensure that decisions on medical matters of wide general import are not taken without proper consultation with those who will be affected.

Circulars

The committee do no more than recommend that the Health Departments should keep the number of directions to a minimum.

They do not ask the Ministry to adopt the Scottish practice and in future issue circulars only to regional boards and boards of governors—never direct to management committees. They think this would put the regional boards to a lot of unnecessary work which would increase the cost of the service without necessarily increasing its efficiency.

Regions and Groups

Any extensive rearrangement of regional boundaries, or the creation of new regions would, it is felt, be wasteful and undesirable.

As for hospital groupings, the committee would like the larger groups to be broken down. Where this cannot be done, the management committee should delegate more responsibility to the hospital secretaries in the group, or should strengthen the position of some of its house committees. This, however, should be quite exceptional. House committees are doing excellent work; but in the ideal hospital group there is insufficient room for two bodies (management committee and house committee) with executive and spending powers.

The committee think it preferable for mental hospitals and mental-deficiency institutions to be managed separately and not in combination with one or more general hospitals.

Committee Work

There is a real danger of the administrative side of the N.H.S. getting bogged down in a morass of committees. Any unnecessary committee work is an unmixed evil.

> "Accordingly we recommend that all Management Committees and Boards of Management should now review their arrangements with the aim of simplifying their committee structure and reducing the volume of work, for example, by increased delegation of authority to responsible administrative officers. We are confident that this delegation would be facilitated if the hospital secretary were given a higher status in hospital administration and if the post of hospital secretary were to become a normal starting point to a hospital administrative career at group or regional level."

Appointment of Boards

The committee hold that the Health Minister must reserve the sole right to decide who shall be appointed to the regional boards. He could not accept an arrangement which would bind him to accept the nominations of the outside bodies concerned.

Medical Membership of Boards and Committees

Should doctors serve on administrative bodies? The committee are against exclusion of doctors. But they were surprised to find that in one board the proportion of medical members has reached 42%, and they think that, *unless circumstances are quite unusual, it should not exceed 25%*.

Current Expenditure

Rewards for Efficient and Economical Management.—Direct financial rewards for underspendings could not be made to one management committee in a region without injustice to others which have budgeted closely and spent up to the limit of their estimates.

Block Grants.—The weight of argument is against the adoption of block grants to meet current expenditure in the hospital service. The analogy with quinquennial grants to universities is not really a valid one, because universities have important revenues of their own and their grants are truly grants-in aid. Moreover there is a big difference in scale between £25 million a year for universities and £320 million for hospitals.

Unspent Balances.—It has often been argued that, to encourage them in economy, hospitals should be allowed to carry forward their unspent balances. But the committee agree with the Select Committee on Estimates (1950–51) when it said:

> "... the amount of money included in a year's estimates of a hospital authority was not the year's income of that authority, but was merely the limit of permission to spend. When a saving has been made on an estimate it generally means that the authority has found itself able to provide the service in question at a lower cost than was allowed for in the estimate; it follows that the Ministry ought not, in the absence of some special reason, to approve an estimate in the following year for the same purpose and of the same size as before."

Capital Expenditure

"Having regard to the advanced degree of obsolescence of many hospitals in this country, and to the very large arrears of capital expenditure resulting from the virtual cessation of hospital building since 1938," the committee suggest £30 million a year as a desirable rate of capital expenditure at which to aim over the seven years succeeding 1957–58. Of this £30 million some 10% should be used specifically for revenue saving schemes.

The maintenance of assets is of great importance, and regional boards should be responsible for ensuring that the fabric of the hospitals in their region is being suitably maintained.

Block Grants and Carry over of Balances.—The arguments for these are not deemed strong enough to warrant a recommendation involving a revolutionary change in Government finance. The committee welcome the innovation whereby the Health Minister recently announced probable capital allocations for three years ahead.

Hospital Costing

Costing systems should be regarded not as a means of imposing restrictions but as a means of ensuring that the best value is obtained for money spent. The committee think that departmental costing should be started they had peripheral vascular disease and that their presenting symptom was *intermittent claudication* Since dilatal stimulates gastric secretion, patients with peptic ulcers were excluded, and, as the makers suggest that it is unwise to give dilatal to patients with angina or with hyperthyroidism, these too were excluded Instead of using a random distribution table to select those who should have the active drug and those who should have inactive placebo tablets, it was decided, in consultation with a statistician, first to divide the patients into separate groups according to the nature of any previous treatment Three groups according to previous treatment were required

(1) Those patients who had had no previous treatment for their intermittent claudication

(2) Those who had been given tolazoline hydrochloride ('Priscol')

(3) Those who had been treated by sympathectomy

Each member in each group was then paired off with a patient of similar age in the same group One member of each pair was given the active drug and the other the placebo The patients were unaware of the activity of the preparation with which they were supplied 2 of the patients taking the placebo tablets had to be dropped from the trial because of illnesses unrelated to their peripheral vascular disease Thus 50 patients completed the trial, 26 of them taking dilatal and 24 acting as controls Various tests were applied to individual legs Since 1 of the patients taking dilatal was an amputee, the reported results refer to 51 legs in the trial group and 48 legs in the controls

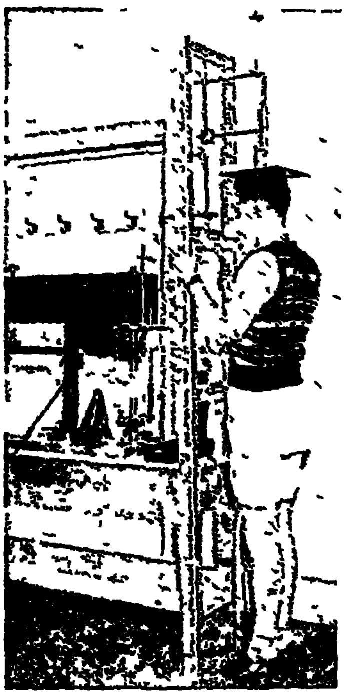

Fig 1—Patient ready to perform exercise test

Each patient made two visits to hospital for the purpose of this trial On the first visit, after being subjected to the various tests described below, the patient was given a tablet of the drug or of the placebo according to whether he was selected for the trial or for the control series, and was observed for half an hour In this way it was possible to ensure that no patient who was going to take dilatal was hypersensitive to it In fact, none of the patients showed hypersensitivity to dilatal The patients were given a supply of tablets to last 9 weeks, together with instructions for taking them At some time between the 8th and 9th week the patient made his second visit to hospital, where he was subjected to the various tests for a second time and asked to state whether in his opinion the course of tablets had made him better, not affected him, or made him worse If in the patient's opinion he was better he was asked to estimate the increase in his walking distance

Acute Clinical Experiments

In 12 patients the immediate effect of dilatal on the blood-flow in the calf muscles at rest was observed The patient rested supine on a couch At the end of about half an hour, when a basal rate of blood flow in both legs had been established, dilatal was given, and the subsequent calf-muscle blood-flow rates were observed every 15 minutes for 2 hours In these tests different doses of dilatal were used, 6 patients received 2 5 mg by mouth, 3 patients 5 mg by mouth, and 3 patients 5 mg intramuscularly

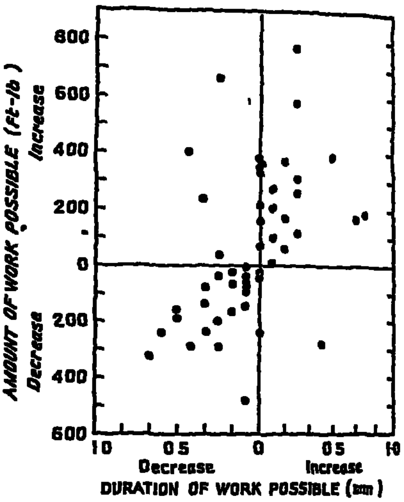

Fig 2—Change in amount and duration of work possible by each leg separately after course of dilatal

Experimental Detail

Muscle blood flow measurements were made with a mercury-in rubber strain-gauge type of plethysmograph similar to that described by Whitney (1953) This was applied to the calf, and the observed flows (calculated as ml per 100 g per min) assumed to represent muscle blood-flow (Grant and Pearson 1938) Venous occlusion was secured by inflation of 7-in wide rubber cuffs incorporated in the legs of a specially made pair of "*shorts*"

The exercise test was made both before and after the 8-week course of either the drug or the placebo On arrival at the clinical laboratory the patient was weighed and prepared for the test by fitting on him the necessary pieces of apparatus A rest of an hour was allowed, during which the patient sat at ease on a chair He next stood up and steadied himself by holding on to the two vertical uprights seen in fig 1 His left leg was tested first As soon as a steady resting blood-flow could be observed, the patient was asked to lift the leg not under test clear of the ground by flexing the knee on that side, and then to raise his body up on to the toes of the side being investigated and down again in time with a metronome (each cycle being timed to last 2 sec) Care was taken that the patient did not assist himself by using his arms He continued to go up and down on his toes in time with the metronome until either the pain of intermittent claudication became so severe that he could do no more or until he had exercised for 2 minutes Immediately the period of exercise stopped, the patient stood still with both feet on the ground The blood-flow was measured from immediately after the exercise until reactive hyperæmia had passed After a rest of 5 minutes the right leg was tested in a similar way

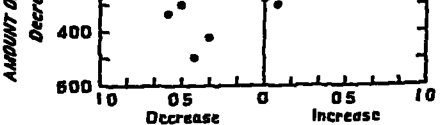

Fig 3—Change in amount and duration of work possible by each leg separately after course of placebo

They doubt whether the work of the Dental Estimates Boards could be done in ways less expensive in money or man-power.

A Comprehensive Hospital Eye Service?

There is certainly scope for some further development of the hospital eye service, but the weight of evidence is against abolishing the supplementary ophthalmic service and substituting a comprehensive hospital service.

Charges to Patients

The committee's rejection of a boarding charge for hospital patients has already been mentioned. Similarly in the practitioner and local-authority services they do not advocate new charges. (Miss Godwin would abolish existing charges.)

Charges for Dentures.—The present charges should be retained so long as there are not enough dentists to meet potential demands.

Charges for Dental Treatment.—These seem to be impeding a number of people from using the general dental service, and the reduction of their incidence should have the highest priority when resources become available. Meanwhile the committee strongly favour the proposal that if financial conditions permit, "the dental treatment charge should be refunded to patients who have received comprehensive treatment, been made dentally fit, and have sought treatment within a specified period of time (say, once every 12 months)." This would enable people to contract (as it were) into a free service and would make an effective contribution to prevention.

Charges for Spectacles.—It seems that these form a barrier to a proportion of the people who need to make use of the service, and priority (second only to adjustment of the dental treatment charge) should be given to a substantial reduction.

The Shilling Prescription Charge.—Removal of this charge would not, at present, improve the working of the service to an extent commensurate with the cost.

Local Health Authorities

In the best interests of local government, the cost of local health services should be shared equally, as at present, between the local rates and the Exchequer. But the committee think that the lack of any Exchequer grant towards the running costs of residential accommodation for the aged "will become increasingly an obstacle to the smooth development of the hospital and local authority services" and may ultimately distort the pattern of the N H S.

Hence they recommend that, as soon as circumstances permit, the existing Exchequer subsidy towards the cost of new residential accommodation under the National Assistance Act be abolished, and that instead the net expenditure (both capital and current) incurred in providing all residential accommodation of this type should attract a 50% Exchequer grant. In return, the Health Ministers could require local welfare authorities to develop their services on a scale commensurate with the needs.

Prevention

So far as the N H S vote is concerned, the committee "know of no wide fields on which large sums of money might now be spent so as to bring the preventive services more into line with the curative services.

" those who have criticised the Health Service for spending far too much on disease and far too little on prevention have tended to overstate their case. It is true that a number of preventive health measures could be initiated, with advantage, outside the National Health Service, one of the most important of which might be the elimination of air pollution. It is true also that some of these measures might cost a great deal of money."

Within the health service, however, they would like to see special attention given to (1) development of the home health services, (2) inquiries "designed to reveal the broad fields in which preventive medicine might be extended profitably," and (3) development of the chiropody service.

Maternity and Child Welfare Services

The maternity services are in a state of some confusion and their organisation should be reviewed soon. New thought is needed as to the rôles of the local authority clinic, the practitioner, and the outpatient department.

Care of the Aged

The committee agree with those who say that it is the "inadequacy" of the services, and not the form of administrative organisation, which is the root cause of the problems now arising in the care of the aged. It is perhaps this inadequacy that has led some to advocate "half-way houses" to fill the gap between local authority and hospital provision, and, though they are far from criticising the very useful half-way houses set up by voluntary organisations and others, the committee do not wish the notion to develop that there is a gap that can be filled only in this way.

Ambulances

This service should not be transferred from the health authorities to the hospital authorities.

Whitley Council Machinery

Among hospital authorities there is still considerable irritation at their not having more discretion to determine rates of pay, to reward staff for outstanding efficiency, and to make bonus payments to employees for whom there is no promotion outlet. But the loss of the autonomy formerly enjoyed by hospital authorities in this field is an inescapable result of the introduction of a national service. The Whitley Council agreements themselves need not always be rigid and inflexible, and the committee think that they should allow a measure of flexibility to meet local variations whenever the need arises—a problem faced and solved by many large scale undertakings. This flexibility, however, should be built into the national agreements and not left to the discretion of individual managing bodies, who might compete between themselves for man-power.

An Intelligence Service for the N H S

The Health Departments are advised to set up a Research and Statistics Department. This would be the Departments' intelligence branch, working with their administrative and medical staff, and it would constantly search for information which would enable administrators to make right decisions for future development.

Coöperation within the Service

Coordination is needed at three levels: (1) centrally, (2) where national policies are applied to local circumstances, and (3) where individual workers must cooperate to help a particular patient. The committee put little faith in new coordinating machinery: "in the areas where cooperation is still lacking, what is now needed more than anything else is a change of heart among those concerned, and particularly, we feel, on the part of hospitals." Further improvements in cooperation will be achieved chiefly at the "working level." Besides recommending regional boards to review their arrangements for consulting the medical profession, they propose that the medical officer of health or one of his staff should have an honorary appointment on the medical staff of a hospital, taking charge of outbreaks of infection.

Final Comment

"Looking to the future, it is clear that there are long-term problems of high importance confronting the National Health Service, not a few of which can only be solved by the medical profession itself, and which will call for all the qualities of statesmanship and adaptability that it can command."

tion, which may show spontaneous remission or changes in severity from day to day

The fact that the patients on dilatal estimated that they had improved in the distance that they could walk to an extent which was significantly better than the improvement claimed by the controls, whereas our tests of exercise tolerance did not show any such statistically significant difference between the two groups, led to a critical assessment of the tests to find if some salient point was being missed A possible source of error might be that dilatal produced a very transient effect For instance, if after the administration of a tablet the blood-flow improved for only a few minutes, the improvement might be noted by the patient but missed by our tests applied about an hour after the last tablet had been taken by the patient Consequently twelve acute experiments were made in which the blood-flow in the legs at rest was measured over $2^1/_2$ hours during which dilatal was given Table II shows that the resting blood-flow increased in 6 of 12 patients In 2 of the 6 patients the blood-flow increased only in the calf muscles of one leg The duration of the transient improvement was such that it might well have been missed by our tests

It seems possible, then, that the subjective improvement claimed by some patients receiving dilatal may have been real But the transient nature and short duration of this improvement indicate that more detailed information is required about the blood-levels of dilatal if a satisfactory dose frequency is to be worked out The fact that only some patients tested in the acute clinical experiments responded to dilatal may be due either to the fact that not all patients absorb dilatal equally efficiently or to the fact that the blood-vessels of some patients respond to dilatal by dilatation whereas those of others do not These factors require fuller investigation before the true value of dilatal can be assessed

It has been shown, then, that dilatal can bring about a transient increase in resting muscle blood-flow in some patients This does not necessarily mean that any increased tolerance to exercise—i e, ability to do more work before being stopped by claudication pain—will follow It was thought worth while to examine the relationship between the improvement in resting blood-flow and exercise tolerance in our patients to find whether an improvement in the blood-flow was reflected by a corresponding improvement in exercise tolerance Such was not invariably the case, since in many patients the resting blood-flow improved without any improvement in exercise tolerance Statistically there was no significant correlation between improvement in resting blood-flow and change in exercise tolerance ($r = 0\ 022$)

Summary

A clinical trial was made of the effectiveness of dilatal in the treatment of intermittent claudication 50 patients completed the trial, 24 being controls

There was a statistically significant subjective improvement in the treated patients, but this improvement could not be confirmed by objective tests of blood-flow

Acute clinical experiments showed that dilatal produced a transient increased resting blood flow in the calf muscles of some patients It therefore seems to be necessary to determine by individual clinical test which patients will respond to dilatal

The 'Dilatal' (now known as 'Perdilatal') was supplied by Messrs Smith & Nephew

REVERSAL OF PULMONARY HYPERTROPHIC OSTEOARTHROPATHY BY VAGOTOMY

GEOFFREY FLAVELL
F R C S, M R C P
ASSISTANT THORACIC SURGEON, LONDON HOSPITAL

IN an exhaustive review of osteoarthropathy Mendlowitz (1942) grouped the ætiological factors under the headings "pulmonary," "cardiac," "hepatic," "gastro intestinal," and "miscellaneous", and these factors covered a very wide range including roundworm infestation, cirrhosis of the liver, myxoid tumour of the right auricle, and thyroidectomy Mendlowitz also discussed the theories of causation under the titles "trophic," "circulatory," "toxic-infective," "mechanical," "toxic mechanical," "anoxic," and "miscellaneous" His conclusions were not very different from those of Hippocrates, who first described the condition in the 5th century B C As West said in 1897, "clubbing is one of those phenomena with which we are all so familiar that we appear to know more about it than we really do"

Hypertrophic osteoarthropathy has been described in association with many conditions, but it is found most typically as a secondary manifestation of chronic pulmonary or cardiac disorder, such as severe emphysema, bronchiectasis, or congenital heart disease, and yet it is extremely rare in chronic pulmonary tuberculosis Its connection with bronchial carcinoma is well recognised, and clubbing of the fingers and toes, with or without pains and sometimes effusions in the wrists, elbows, ankles, and knees, may long precede pulmonary symptoms The patient is often treated for "rheumatism" or "arthritis" for as long as twelve months before a neoplasm is revealed by radiographic examination of the chest Such growths, though sometimes very small, may be accompanied by rarefaction of the shafts of the long bones, deposition of new subperiosteal bone at the muscular insertions into the shafts and at the diaphyseal ends, and quite substantial effusions into the related joints, as well as clubbing All these changes are due to increased vascularity, in particular an increase in the terminal arterioles, and, Mendlowitz (1942) holds, "an increase in blood flow per unit of tissue caused chiefly [in the case of simple clubbing] by increased digital arterial pressure" The pain to which these pathological changes subject the patient is commonly not only the first symptom but also much the worst, robbing him of sleep for long periods Since such bone changes are hardly ever associated with tuberculous lesions their presence may virtually end all doubt as to whether an isolated abnormal opacity in a chest radiograph is due to a neoplasm

Alvarez (1948) estimated that as many as 50% of resectable bronchial carcinomas were accompanied by arthropathy, and suggested that articular symptoms were as common as respiratory Hansen (1952) reviewed 100 cases of bronchial carcinoma and found 12 (excluding 5 with bone metastases) with joint pain, and such pain was the presenting symptom in 4 In my own experience I would place the prevalence of joint pain in bronchial carcinoma as 5–10%, and in these cases careful inquiry usually shows that arthralgia was the first abnormality noted (Flavell 1953)

It has long been known that resection of the growth is followed instantly by cessation of all pain, no matter how long this has been present, and that secondary changes such as clubbing of the nails and redness and swelling of the nail-bed at once resolve, the shape of the nails returning to normal as the nails grow out This remarkable fact has led to much speculation but no conclusion, and hitherto no explanation of the mechanism involved has proved satisfactory It is, for example, The platelet retraction factor ("retractin") is, thus, clearly distinguishable from other constituents of platelets It can be also isolated from brain tissue, and in lesser amounts from spleen and liver, but not from erythrocytes It is resistant at 56°C for at least two hours and stable indefinitely at $-20°C$ Studies for the identification of the factor, very likely a lipoid substance are in progress

SERGIO I MAGALINI
MARIO STEFANINI

ELECTRON-MICROSCOPY OF ATHEROMA

SIR,—Dr Loveno (Jan 14) asks me what reason I have for assuming that the material shown in my letter of Dec 31 is really collagen

Collagen is characterised chemically by a specific high content of the amino acid hydroxyproline (13 6%[1]) The hydroxyproline content of other proteins is low, in fibrin we found 0 12%

In whole cornea we found a hydroxyproline content of 7 1%,[2] so the collagen content is $\frac{100}{13\ 6} \times 7\ 1 = 52\ 2\%$

Examination of corneal connective tissue by means of the electron microscope shows that it contains—besides cells and ground substance—exclusively fibrils as shown in my letter, the fibrils are uniformly thin (300-350Å) and have a cross banding of about 220Å Considering this we may safely assume that the fibrils in question are in fact collagenous

We have made hydroxyproline determinations in aortic atheroma in two cases and found values of 4 25 and 4 26% (signifying a collagen content of 31 2 and 31 3%) In an unaffected part of one of the aorta under investigation we found 2 9% hydroxyproline in the intima and 2 66% in the whole wall (corresponding to 21 3 and 19 8% collagen)

Thus collagen is a substantial component of the aortic wall, probably the development of atheroma is accompanied by an increase of collagen in the form of unusual thin fibrils

University of Amsterdam

A VAN DEN HOOFF

PROTOPHRENIA

SIR,—May I thank your correspondents for encouraging and helpful criticism Also, I need a few lines to answer Dr Gellner (Jan 7), this I do reluctantly and only because her strictures, which anyone could refute reading the work freshly, were separated by five weeks from my paper (Dec 3)

Actually in the paper I discussed in detail, which I shall not re state, the only valid objection Dr Gellner raises This was that, unlike the cases with demonstrable organic pathology, the "residual" group among the defective children in my series might not have been a reliable sample of such cases in general Dr Gellner, however, advances this with two strange assertions

One is that only feckless parents would seek hospital care for an imbecile child if he looks anatomically normal Plainly from this, she knows nothing of the burden such a misfortune may bring to a working-class home A chat with an urban doctor, or simply with the parents of children just like this at her hospital, might be enlightening for her

Her second assertion, which is no less extravagant, is that the proportion of my "residual" cases was unduly small In outpatients, she says, "residual" cases outweigh the organic Which outpatients, I wonder? Anyone with experience of children so very severely defective as these, all with I Q s below 50, is aware that the great majority present obvious organic disease In fact, I quoted other work to show that my proportions tallied with modern findings

Oddly enough, most of Dr Gellner's long letter is devoted to her own theories, which directly contradict this statement of hers Clinical signs of organic disease of the nervous system exist, she declares, in all cases of mental defect, "residual" or otherwise, though they are only to be found by the esoteric methods of neurological examination prescribed in her unpublished papers I am ignorant of these, but having read other letters to the medical press from Dr Gellner I can see why she dismisses my data about emotional adversity being one possible cause of mental defect

A single child's case[1] was enough to convince her that defect arises not from inadequacy of the higher cerebral centres but from the midbrain Subsequently,[2 3] she satisfied herself that this was indeed so and, in particular, that the vital lesions lay constantly in the corpora quadrigemina and the lateral geniculate bodies

HAROLD BOURNE

HOMOSEXUALITY

SIR,—It seems to me that Dr. Comfort's article (Jan 21) is a classical example of pseudo scientific myopia and that he has not the ability to see the picture whole

A moral code is a human device for curbing animal passions so that man can live in communities and has to be learnt by each individual painfully, a fact from which Kinsey profited, but did not spot, we are all potential thieves, homosexuals, liars, and gluttons A code is the most important single factor in the natural history of man as a gregarious animal It dominated his psyche long before time was recorded in words It has tremendous survival value and a society without a code disintegrates, a modern example of which is not far distant To anyone who is interested in the method of disintegration in times of crisis I recommend Sir Edward Spears's *Assignment to Catastrophe*

Although these codes were formed over the centuries to meet man's biological needs and necessities, they have become integers which have to be accepted whole or not at all The fictitious Raffles, a professional thief but a perfect gentleman in other respects, is a psychological impossibility From what was said in Parliament recently the case of the missing diplomats affords an example of homosexuals who were unreliable in every way, which is not to say that homosexuals may not have great ability, especially artistic ability Dr Comfort gibes at the emotional words, phrases, and sentiments in the B M A report, but emotion is the very essence of a moral code, if people did not feel emotionally about it it would cease to dominate and combine I wonder whether, if somebody stole Dr Comfort's personal possessions, he would be so nonchalant about that breach of the moral code as he appears to be about homosexuality

Dr Comfort adduces the homosexual behaviour of his laboratory animals as in some way palliating homosexual behaviour in man He does not mention that throughout the mammalian world the young learn largely by imitating adult behaviour When he sees no harm in adult males indulging in private in mutual masturbation, intercrural intercourse, sodomy, and/or fellatio, the unholy quartet which constitute the euphemism homosexuality, has he not thought that this behaviour is bound to be imitated by many of the young?

A very able Departmental Committee have been hearing evidence on this subject for nearly a year and will soon be reporting Personally I very much hope that they will not recommend any changes in the laws governing homosexuality, although I think these laws might be implemented with more humanity and common sense I should have thought that it would have been better to await their report and not start shouting through the keyhole of their retiring-room, but as you have allowed Dr Comfort to do so I hope you will let me effusions In the last three the hila were not disturbed but the vagus on the side affected (right in case 3 and 5, left in case 4) was isolated as far away as possible and cut Equally dramatic relief and disappearance of joint swelling followed

---

[3] Gellner L *Ibid*, ii 392

It would seem therefore that the manifestations of pulmonary hypertrophic osteoarthropathy are caused by a neural reflex passing from the affected lung in the fibres of the vagus nerve, and can be terminated by severing the vagus even when the related growth is irremovable

This finding casts an interesting light on the function of the vagus and the nature of osteoarthropathy, and it affords a certain method of relieving the persistent and distressing pain of osteoarthropathy

Summary

In cases of bronchial carcinoma associated with hyper trophic osteoarthropathy, severing the vagus nerve on the side of the affected lung has promptly dispelled the symptoms and signs of osteoarthropathy

Case 1 was referred by Dr S Locket, case 2 by Sir Horace Evans, case 3 by Dr A E Clark-Kennedy, and cases 4 and 5 by Dr J M Gray

A NEW WAY OF TREATING FLAT FEET IN CHILDREN

ARTHUR J HELFET
B Sc Cape Town, M D, M Ch Orth Lpool, F R C S
ORTHOPÆDIC SURGEON, GROOTE SCHUUR HOSPITAL, CAPE TOWN

Two kinds of flat feet are found in children Congenital pes planus is the rarer of the two because most children with flat foot acquire it by everting the heel of an otherwise normal mobile foot (fig 1)

The normal foot bears weight chiefly at three points the heel and the heads of the first and fifth metatarsals (fig 2) This three-point weight-bearing is converted into a tripod by the longitudinal and transverse arches If the foot is flat or everted, the child bears weight as well along the inner border of the foot, which is not suitable for weight bearing The gait therefore becomes awkward The child may try to compensate by walking "pigeon-toed," and some who walk in this way and start with a mildly everted heel manage to reform the foot If the foot cannot compete with the eversion, the child walks with the feet splayed outwards—"Charlie Chaplin" gait In either case there is a tendency to tread down the stiffening of the outer wall of the heel seat of the shoe and to wear down the outer side of the heel of the shoe (fig 3)

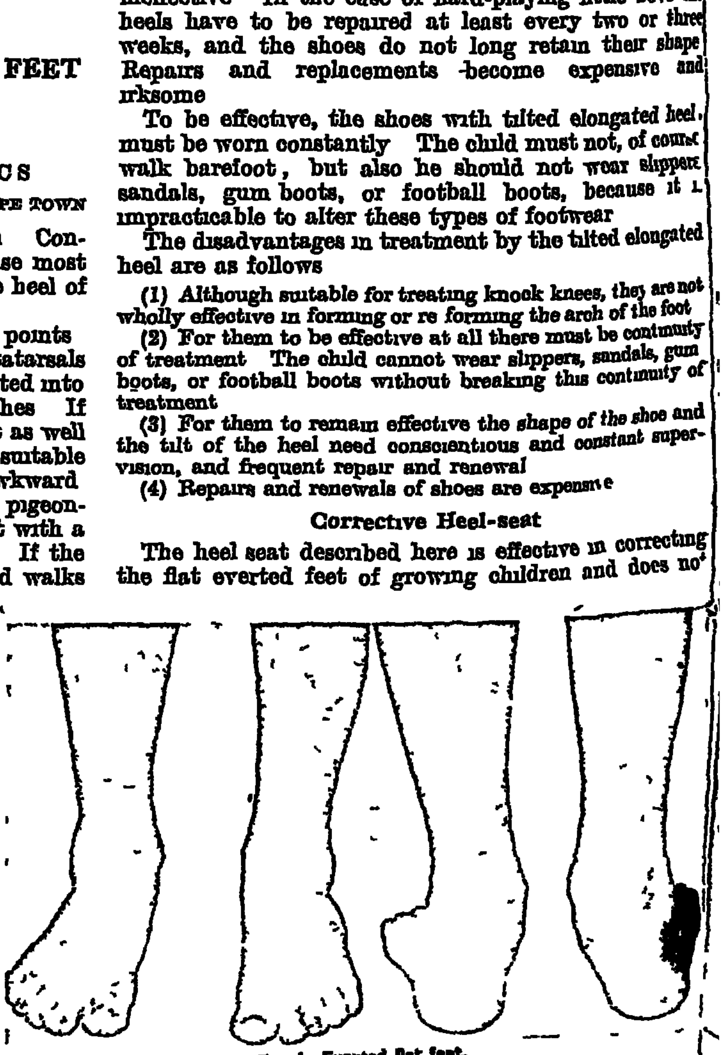

Fig 1—Everted flat feet.

Established Methods

Some pædiatricians believe that flat feet in children correct themselves spontaneously a visit to any orthopædic department dealing with adults or, more especially, to any military recruiting depot or orthopædic unit will rapidly dispel such an illusion

There are two established approaches to the problem

Arch-supports

For many years Continental schools have prescribed rigid arch supports These do raise the arch, but only by persisting with the fourth and unnatural weight bearing area (fig The consequence is that the arch does not devel strength and collapses once more when the supp is removed Because of this method of treat flat feet in children rigid arch-supports were standard issue in the German army of the 1939- war

In other words, once a child is used to arch supp it cannot do without them *Ordering arch supports fo* child is more than a prescription—it may be a li sentence

Tilted Elongated Heel

The second method, which is almost universal English-speaking countries, is to correct eversion the Thomas heel—i e, by tilting and elongating heel of the shoe on the inner side If the heel snugly, the tilt does correct the eversion Unfortunate to protect the welt one has to elongate the heel on inner side, and so the forefoot is also inverted slight Consequently, however long the child wears these alte shoes, the foot and heel relapse in some degree afterward

The tilted elongated heel has other disadvantages, the main one being that it is difficult to preserve the sn fit of the shoe round the child's heel The foot tends slip down the slope to the outer side of the shoe, deformin the outer wall of the heel-seat and wearing the heel dow along the outer border (fig 3)

Once the grip on the heel is lost, the shoe must b repaired or renewed, otherwise the method become ineffective In the case of hard-playing little boys the heels have to be repaired at least every two or three weeks, and the shoes do not long retain their shape Repairs and replacements become expensive and irksome

To be effective, the shoes with tilted elongated heel must be worn constantly The child must not, of cours walk barefoot, but also he should not wear slipper sandals, gum boots, or football boots, because it impracticable to alter these types of footwear

The disadvantages in treatment by the tilted elongated heel are as follows

(1) Although suitable for treating knock knees, they are not wholly effective in forming or re forming the arch of the foot

(2) For them to be effective at all there must be continuity of treatment The child cannot wear slippers, sandals, gum boots, or football boots without breaking this continuity of treatment

(3) For them to remain effective the shape of the shoe and the tilt of the heel need conscientious and constant supervision, and frequent repair and renewal

(4) Repairs and renewals of shoes are expensive

Corrective Heel-seat

The heel seat described here is effective in correcting the flat everted feet of growing children and does no eg supports The abdominal and vaginal surgeons do his part of the operation together, and it is only when the abdominal dissection is sufficiently advanced that the vaginal surgeon takes his station below, his part of the operation merely occupies the last half-hour of the combined proceeding In this way, the expert assistance of the vaginal surgeon is available both above and below The accompanying figure shows the amount of parametrium and paracolpos that we are now removing

I do not propose to enter into the controversial subject of radiation versus surgery as each case must be assessed and treated on its merits

Finally, I propose to publish in the near future a survey of my first fifty cases which will, I hope be of some encouragement to those surgeons who have performed or are contemplating this operation

St Bartholomew's Hospital
London, E C 1 JOHN HOWKINS

PRODUCTION OF CODEINE

SIR,—I suggest to Dr Williams that before he really believes what he wrote about codeine (Jan 21) he asks some chronic sufferers from such conditions as osteoarthritis or rheumatoid arthritis which they prefer for their pain—tab codein co or aspirin Also I would advise him if he should have a bad cough at night to take a dose of linctus codeine co *N.F* for each bout of coughing

Luton D R SNELLGROVE

CŒLIAC DISEASE

SIR,—In his admirable article[1] Dr Sheldon has cited a case of selective absence of lipase as unique May I correct this statement, and draw attention to the cases I have observed[2–4] and also to those reported by McDougall[5]

Indeed, the condition must be fairly common It is well known that the pancreas is a most sensitive organ and that its enzymes may be absent from duodenal juice in quite a number of pathological conditions It is also known that the dysfunction is mostly transitory although in some cases it apparently persists for long periods or even for life. According to common belief the three pancreatic enzymes are equally involved in the dysfunction In contrast with this, it has been found that, while in health a strict parallelism exists in the secretion of the three enzymes,[6 7] in pathological conditions associated with pancreatic dysfunction there is no parallelism, either in rate or in time, between the involvement of the single enzymes Lipase appears to be the most vulnerable of the three This enzyme has usually been the first to disappear and the last to return to normal, whether in infectious fevers, gastro-intestinal disease,[4] the acute toxic form of infantile diarrhœa,[8] or even protein deficiency disease[9 10], and among the reported cases of temporary selective deficiency of one enzyme, that of lipase appears to be the most usual, especially in scarlet fever,[3] but also in other conditions[4 5]

Permanent absence of trypsin[11] and (as Dr Sheldon remarks) of amylase[12] has been reported Of McDougall's[5] 16 cases with reduced activity of lipase alone, 1 took fifteen months to recover after the deficiency, probably of long standing, had led to symptoms of cœliac disease It may be assumed that permanent lipase deficiency may arise in consequence of some condition injurious to the pancreas, whether before birth[13] or subsequently

ANTICOAGULANTS IN A HOT CLIMATE

SIR,—We have been analysing our figures for patients on long-term anticoagulant therapy to see whether we could confirm Dr Tawfic's claim[14] that patients receiving phenylindanedione may bleed more easily during hot weather We had not noticed this tendency and an examination of our records does not reveal it Since such an effect might have been masked by our using a smaller dose of the drug ('Dindevan') we have calculated the maintenance dose required by 10 randomly selected patients

We aim at a prothrombin index of 40–60% The results (see accompanying table) show no consistent alteration in relation to the mean average daily temperature The Egyptian summer is warmer than our own but from our observations it would appear that moderate heat does not affect the dose of phenylindanedione which is required for "long-term" maintenance anticoagulant therapy

University of Cape Town ELIZABETH SCHOLTZ

CORONARY-ARTERY DISEASE

SIR,—It is difficult to assess the real weight of the arguments of Dr Bronte-Stewart and his associates at Cape Town University (Jan 14) before fuller details are known of their very interesting, and apparently most valuable, findings

It will be particularly important to know (*a*) the age of the volunteers, and (*b*) the time-lag between the ingestion of the experimental foods and the testing of the cholesterol content of the blood Regarding (*a*) it is well known that the susceptibility of the cholesterol content of the blood to dietetic factors varies with age, being very low during the first three decades of life, and then increasing with each further decade Regarding (*b*), we know that cholesterol in the human body is rapidly broken down and easily synthesised within quite a short time

But even after clearing up these points, there would still be no absolute proof that it is, as they assert, the high content of unsaturated fatty acid contained in the germ of wheat and maize, and not the vitamin E, which is the decisive factor operating against coronary-artery disease, because all chemically untreated vegetable oils do contain in varying degrees natural tocopherols—i e, vitamin E—with their known biological activity. Nothing but complete elimination of the tocopherols from the vegetable oils before ingestion could substantiate their view Their finding that ground-nut oil fed in hydrogenated form produced a prompt rise in the serum-cholesterol level not only fails to support that

Comments

The heel seats have to be made individually of plastic material from plaster-of-paris moulds of the child's feet and are therefore expensive I hope it will soon be possible to arrange for manufacture of the heel seats in a light, cheap, and durable form and in a wide range of sizes It takes from six to nine months before the average child grows out of any one size Only one pair of heel seats is required at a time, for they can be transferred as shoes are changed

For ordinary flat foot these heel-seats could be prescribed by family and school doctors and dispensed by appliance makers, or by trained employees in any good shoe store If the heel-seat fits the child's heel it is the right heel-seat So prescribed it would relieve some of the congestion in hospital orthopædic departments It may also be used prophylactically in convalescence if the child's feet are weakened by illness or recumbency

I am now convinced that the heel-seat gives us a sure, simple, and economical method of correcting flat, and developing strong, feet in children When we can use a plastic—e g , laminated fibre glass—a thin layer of which can stand big weights, we may be able to use the heel seat also for the flat feet of adults

ELECTRO-ENCEPHALOGRAPHY IN CHILDREN WITH RECURRENT ABDOMINAL PAIN

IN 1912, Still suggested that "masked epilepsy" could account for attacks of sudden abdominal pain in children From the few details provided, the diagnosis is open to criticism on several counts and indeed the suggestion has found few proponents until recently Lately, however, the diagnosis has won some adherents abroad (Klingman et al 1941, Moore 1944, Livingston 1951, Blumberg 1954), and a few in this country In Conway's (1951) series abdominal epilepsy was diagnosed once in 243 cases, and Mac Keith and O'Neill (1951) state that as the sole manifestation of epilepsy abdominal pain is rare , but it has been affirmed (Wallis 1955) that "the more commonly it [abdominal epilepsy] is sought the more commonly it appears" Some of these are only single case reports, and the sum total of recorded cases is small The absence of any control series should also be mentioned

The diagnosis of "abdominal epilepsy" is based on some such criteria as the following (Livingston 1951) (1) attacks of abdominal pain followed by exhaustion and sleep , (2) a favourable clinical response to treatment with anticonvulsants , (3) electro-encephalographic (E E G) records considered characteristic of epilepsy

Because of the small number of reported cases and the lack of normal controls, we consider that criteria of diagnosis have not been established and, as part of a wider investigation into the nosology of recurrent abdominal pains in children, they have been under review for some time In view of the recent interest (*Lancet* 1954, 1955) we felt that an account of the E E G findings would be of value

Material

The children were between 3 and 14 years of age We included those who complained of abdominal pains, recurring over a period of at least three months, severe enough to cause some interference with normal activities, and in whom no evidence of organic disease was found The only omission in the series with abdominal pain, as in the control series, was a very small number of children who were suffering from fits but who also had abdominal pain, either as an aura or unrelated to the fits

TABLE I—E E G ABNORMALITIES IN 133 CHILDREN WITH AND 133 CHILDREN WITHOUT RECURRENT ABDOMINAL PAIN

—	With pain	Without pain
Resting record		
Normal	121	120
All abnormalities*	12	13
Resting and evoked		
All abnormalities*	18	13

* Including "focal spikes" (6 in abdominal pain cases and 3 in control series), which may migrate, change site, or disappear (Gibbs et al 1954, Kellaway 1953), and "localised slow activity" (2 in abdominal pain cases and 1 in control series) In neither of these is there definite evidence of an enhanced tendency to epilepsy

Hospital Series

With these provisos, all the children with abdominal pains referred to a hospital outpatient department during a limited period had E E G s taken Over the same period, E E G s were taken of other children of approximately the same ages, from the ordinary run of non acute hospital patients There were 96 children with abdominal pains as defined and 55 patients without abdominal pains

School Series

As part of an investigation of abdominal pains in an unselected school population (Apley and Naish 1956) E E G s were taken from children attending school clinics for routine examination A series of 37 children with abdominal pains was obtained, and 78 of those without pains were used as controls in corresponding age groups

To avoid any possible bias, requests for E E G s were made with no information other than the heading of "hospital series" or "school series," so that all reports were made without knowledge of whether the patient had or had not abdominal pains One of us (C T) made all the reports, and those which appeared in any way abnormal were re examined and discussed

TABLE II—E E G "EPILEPTIFORM" ABNORMALITIES IN 133 CHILDREN WITH AND 133 CHILDREN WITHOUT RECURRENT ABDOMINAL PAIN

—	With pain	Without pain
Definite epileptic		
Resting record	2	5
Resting and evoked	14	14
Definite and borderline		
Resting record	4	9
Resting and evoked	22	22

Results

We found no significant differences between the hospital and school series of children with abdominal pains, and the two groups are therefore discussed together Similarly the hospital and school children without abdominal pains are grouped together for the purpose of discussion In assessing results the difficulty of defining an "epileptiform tracing" arises, and will be briefly discussed later

If all E E G abnormalities are grouped together it is seen (table I) that, comparing children with and without pains, there is almost complete identity on the resting records If, however, evoked responses (hyperpnœa and photic stimulation) are considered to be significant, and are therefore included, there is a slight preponderance

Notes and News

WORLD HEALTH ORGANISATION

THE 17th session of the Executive Board of the World Health Organisation opened at Geneva on Jan 17 under the chairmanship of Dr Sabeeh Al Wahbi, director of Karkh Hospital, Bagdad Iraq, who in his opening address quoted an Arab proverb 'there are two forgotten blessings, health and security,' and said that W.H.O had the duty of helping the world achieve these two blessings

Dr Nicolai Khmelev deputy minister of health of the Soviet Union, announced his country's decision to resume active participation in W.H.O, a decision which the board welcomed warmly The Soviet Union withdrew from W.H.O in 1949, but because the Organisation's constitution does not provide for a country's withdrawal, the Soviet Union and eight countries which took similar action were considered 'inactive members'

BRITISH JOURNAL OF TUBERCULOSIS AND DISEASES OF THE CHEST

To celebrate the 50th anniversary of this journal, Messrs Baillière, Tindall & Cox, the publishers, arranged a dinner which was held in London on Jan. 24 Sir Robert Young said that it had required great courage and vision on the part of the first editor, T N Kelynack, and the publishers to start a journal in a special field in 1906, when specialisation was at a very early stage of evolution But from the first number the journal was approved and supported by the chief specialists in tuberculosis and by the masters of medicine of the time After 27 years Kelynack was followed as editor by Lancelot Burrell whose early death was a great loss to the journal Clifford Hoyle, succeeding him, had recognised that its scope should be enlarged to include other diseases of the chest All these had maintained the critical and philosophical character of the publication and the writings of the present editor, Philip Ellman, showed a critical faculty and wide perspective, which, with his experience of chest diseases—clinical, pathological, and administrative—and his great enthusiasm and industry, contributed to the success of the journal As long ago as 1931 Dr Ellman had suggested the reorganisation of the tuberculosis dispensaries into chest clinics, enlarging their scope and usefulness, and these suggestions had been carried out 17 years later Dr Philip Ellman, responding from the chair, welcomed the guests who included Sir Russell Brain, P.R.C.P, Mr Charles Read P.R.C.O.G, Sir Clement Price Thomas (representing the Royal College of Surgeons), Dr G F Abercrombie (chairman of council of the College of General Practitioners), Dr W E Snell (president of the Tuberculosis Association), Dr J L Livingstone (president of the Thoracic Society), Dr Hugh Clegg (editor of the *British Medical Journal*) Sir Heneage Ogilvie (editor of the *Practitioner*) Dr J G Scadding and Mr Norman Barrett (editors of *Thorax*), and Lord Moran.

Sir John Charles (chief medical officer of the Ministry of Health), proposing the toast of Medical Journalism said that throughout the 50 years of the *British Journal of Tuberculosis* medical journalism had been the tried and trusted recording angel of the achievements of the profession it had given outstanding service in recording those facts as they appeared to the contemporary eye and understanding and in the production and propagation of ideas This constituted a responsibility, a charge, and a challenge which had been accepted with good humour and success The integrity of British medical journalism, the allegiance of its members to the highest ideals of the two professions, had been in accordance with the Hippocratic canon and a model to the world. Dr T F Fox (editor of *The Lancet*) compared medical journals to gardens, in which the workers might be many or few, whole-time, part-time, or jobbing He expressed admiration for the clinicians pathologists, and others who give so much of their time and of themselves, to such work. Their labours too often went unregarded or were taken for granted, but they were in fact the greater part of medical journalism Mr R F West (chairman of the publishers) said that the journal had had two parents—Dr Kelynack and Mr A. A Tindall, who was present at the dinner From Dr Hoyle who had borne the heat and burden of the day through the war, Dr Ellman had received a goodly heritage, but to an illustrious series of editors he had added lustre Never, surely had so much been accomplished in 50 years as in the world of medicine in the lifetime of the journal

DIDCOT RAILWAY DISASTER

AT a meeting of the Devon and Exeter Medico Chirurgical Society on Jan 19 Mr P M C Robbins spoke of the lessons learnt from the Didcot Railway Disaster 7 people were killed at once, 2 more died of multiple injuries soon after admission to hospital, and 1 man died on the way there, from a ruptured pancreas and spleen Of the 54 casualties admitted to the Radcliffe Infirmary, 20 had head injuries (5 major ones), 2 had severe chest injuries (1 with a fractured pelvis and the other with a dislocated hip), and 2 had moderate chest injuries One patient had a crushed leg, and several others also had compound fractures The remainder had minor fractures or lacerations There were no burns or abdominal injuries among them One woman died of a massive pulmonary embolus five weeks after the accident In the case of the patient with the crushed leg gangrene necessitated amputation Incidentally discovered during examination in hospital were 2 cases of pulmonary tuberculosis, 1 of diabetes mellitus, and 1 of leucoplakia of the cervix

Within an hour of the accident the first batch of 15 casualties was arriving at the hospital, where all possible patients had been discharged and admissions cancelled Reception space was found in the casualty department and outpatient hall When all 54 casualties had been admitted there were still 50 empty beds available Two theatres were immediately ready for use Almost the entire hospital staff reported for, or remained on, duty The organisation worked smoothly, and the emergency was all dealt with in twelve hours Mr Robbins had only one serious criticism owing to congestion. information was difficult to come by on the telephone A police radio-car at the site of the accident in direct communication with another car at the hospital would have provided a much more efficient information service

Prof L G W Hill, has been appointed an honorary physician to the Queen in Scotland, in place of Dr A Greig Anderson, who has resigned

Royal Society of Health

On Wednesday, Feb 15, Dr Arnold Brown will speak on the Contribution of the Medical Officer of Health towards Industrial Health, and on Wednesday, March 14, Dr Kenneth Soddy will open a discussion on the Prevention of Break-up of Families Both meetings will be held at 2 30 P M at 90, Buckingham Palace Road London, S W.1

M O H for Bristol

Dr R C Wofinden has been appointed medical officer of health for Bristol in succession to Dr R H. Parry who has retired Since 1947 Dr Wofinden has served as deputy M O.H for the city and as lecturer in preventive medicine in the University

Dr Wofinden, who is 41, was educated at Rotherham Grammar School graduated M B Lond with honours in 1937 from St Mary s Hospital Medical School Two years later he took his M D in State medicine and the D.P H He has held posts in the public-health services of Rotherham and of Bradford For his investigation into problem families in Bristol he was made an honorary life fellow of the Eugenics Society In 1945 he was awarded the diploma of public administration of the University of London. Two years ago with a World Health Organisation travelling fellowship, he studied health and welfare services in Holland and Scandinavia tion (Daniels 1949) invaluable, and we have applied this method in 304 cases since the beginning of 1952

Technique

The operation should be done by an experienced surgeon, because vulnerable structures lie in the operation field

The biopsy is done on the more severely affected side, judged radiographically, or, if both sides are affected equally, on the right side After injection of local anæsthetic the skin and platysma muscle are incised for 3–4 cm parallel with, and 1–2 fingerbreadths above, the clavicle The superficial fascia is incised along the lateral border of the sternocleidomastoid muscle, which is retracted medially exposing the pad of fat on the anterior surface of the scalenus anterior muscle Care should be taken to avoid injuring the lymphatic duct on the right side and the phrenic nerve and the thoracic duct on the left side Sometimes the omohyoid muscle lies rather low, in which case the pad of fat is grasped above that muscle The pad is drawn forward and carefully examined In the pad lymph-nodes (which are part of the mediastinal system) may be visible or palpable, and these are removed, but, if no node is detected, as much as possible of the pad is removed The incision is then closed

The discomfort caused to the patient by this operation is very slight

Histological Findings

In sarcoidosis the lymph-node tissue is diffusely, and often densely, infiltrated by discrete, usually spherical, epithelioid-cell clusters of roughly uniform size Some of these clusters contain giant cells of the Langhans type in which we have occasionally found inclusions (either Schaumann or asteroid bodies) There may be slight central coagulation necrosis, chiefly fibrinoid, and also small areas of fresh caseous necrosis in occasional clusters of epithelioid cells Gross caseous necrosis is not found Collagen fibres, commonly hyalinised, appear first at the periphery of the epithelioid-cell clusters, which are gradually transformed into hyaline masses In advanced cases some epithelioid-cell clusters may not be hyalinised, whereas others are partly or fully hyalinised

Histological differentiation between sarcoidosis and other diseases, notably tuberculosis, is sometimes difficult This differentiation is based chiefly on the presence and degree of caseation, but if no acid fast bacilli are found it is often impossible to distinguish histologically between sarcoidosis and tuberculosis

Sarcoidosis should never be diagnosed on the basis of the histological findings alone

Results

The results of retroclavicular block dissection in 304 cases are shown in the accompanying table In only 4 cases were no lymph-nodes found In 130 cases histological examination showed healthy nodes or non specific lesions, but in 168 cases (55%) this examination helped to establish the diagnosis Of 237 patients with clinical and radiographic evidence of sarcoidosis, biopsy by this method supported the diagnosis in 148 (62%)

PRELIMINARY AND FINAL DIAGNOSES IN 304 CASES

Preliminary diagnosis	No of cases	Diagnosis after biopsy					No lymph nodes found	Lymph nodes healthy or lesion non specific
		Sarcoidosis	Pulmonary tuberculosis	Hodgkin's disease	Carcinoma of the lung	Uncertain (tuberculosis or sarcoidosis)		
Sarcoidosis	237	148	Nil	1	Nil	Nil	3	85

CHRONIC PAROXYSMAL HYPOGLYCÆMIA
(WHIPPLE'S SYNDROME)
A FIFTEEN-YEAR CASE-REPORT

E H R ALTOUNYAN
M D Camb, F.R C S
DIRECTOR, ALTOUNYAN HOSPITAL, ALEPPO, SYRIA

THE second World War, the natural reluctance of the patient to submit to an operation hitherto unknown in this region, and the diffidence of the surgeon about operating on a patient who seemed perfectly normal for months at a time have given me the opportunity of *observing for fifteen years a patient* whose pancreas contained a solitary insulin tumour Removal of this has apparently arrested slowly progressive mental degeneration, restored the blood-sugar level to normal permanently, and enabled her to resume full time work on the hospital staff

Although several hundreds of such cases have by now been reported, I believe it is still worth while publishing each case verified by either operation or necropsy Moreover at operation the appearance of a "normal" pancreas may discourage the surgeon from proceeding with a blind partial excision and thus make him miss a radical cure

Case-report

A female hospital worker, aged 21, was found, on the morning of June 21, 1939, in coma on the floor by her bed Fortunately my first assistant, Dr A Hovnanian, found that her blood sugar level was 27 mg per 100 ml and the administration of glucose led to prompt recovery During the fifteen years that followed this first attack, until the day of her operation on Oct 1, 1954, despite every effort by diet and frequent meals to keep up her blood sugar level, she went into coma frequently, and thirty two blood sugar estimations were made, giving 27–64 mg per 100 ml and once 84 mg per 100 ml A glucose tolerance test in 1949 gave 39–155–38 mg per 100 ml, and in 1952 55–105–59 mg per 100 ml Gradually the patient became less and less able to work, and mental degeneration set in During her last attack, immediately before operation, she became maniacal and was given the choice of either submitting to operation or being transferred to a mental hospital

Operation (Oct 1, 1954)—Blood sugar levels were as follows 40 mg per 100 ml immediately before operation, *230–120–122 mg per 100 ml during operation,* when glucose was being continuously administered, and 169, 160, 175, 154, and 127 mg per 100 ml on successive days after operation Sixteen subsequent blood sugar estimates were within normal limits, and the patient made a good recovery and is now back on full work Her mental improvement was noticed immediately and has been maintained during the past year

Comments

The one point I wish to emphasise about the operation is that, the completely exposed pancreas appeared to be perfectly normal, without any reddish nodules or nodules of any kind palpable by the exploring finger on the anterior surface In view of the history it was decided to remove the tail and body of the pancreas, which was accordingly lifted clear of its bed and turned over On palpation of the head between finger and thumb a hard nodule, perfectly round and just over 1 cm in diameter, with a thin calcareous shell, was discovered embedded in the substance of the head This nodule was removed

CLINICAL CANCER RESEARCH*

D W SMITHERS
M D Camb, F R C.P, F F R

PROFESSOR OF RADIOTHERAPY IN THE INSTITUTE OF CANCER RESEARCH ROYAL CANCER HOSPITAL, AND DIRECTOR OF THE RADIOTHERAPY DEPARTMENT, ROYAL MARSDEN HOSPITAL

RESEARCH is sometimes used in a most practical attempt to find an immediate answer to a specific problem, but basic or fundamental research is more truly the expression of a state of mind It is an attitude, a curiosity about patterns, relationships and mechanisms, an urge to understand Its methods are observation, experiment, and contemplation It takes its inspiration from Nature and not from need, its proper reward is understanding, not practical application This seems to me to apply to cancer no less than to any other subject —and to some clinical cancer research no less than to non clinical I do not say that application is unimportant, merely that it should not be the primary concern of the basic research worker and that when it does become so his work is apt to suffer

Those of us whose lives are intimately bound up each day with urgent human problems sometimes have great difficulty in remembering that research departments, if they are to flourish, must protect their independence from those of us who wish to put their work to use, and that they must not allow themselves to become too concentrated on the solution of practical problems The business of making research effective is not primarily theirs and needs separate thought and organisation The links between basic research and clinical practice in cancer have to be most securely forged if the fundamental research workers are to maintain this desirable state of privileged independence of man's needs, and if their work is to advance the cause of prevention and healing as well as that of science Some medical research must itself have this same freedom to follow nature—in fact the basic clinical research worker is far too rare *amongst us* We could do with many more in the cancer field cloistered, academic, fundamental, and unhurried, on whom we should make no demands for practical results, but from whom, in time, we may hope for some increase in understanding from whatever unlikely direction their inquiry may have led them

Today the directors of large cancer research organisations have a terrific task It is essential that they *should* have complete control of how the research within their organisations is done, but so many special branches of science are involved that if they are to be knowledgeable enough to be effective they cannot, at the same time, possibly have more than the most superficial contact with the whole world of clinical medicine which is most intimately involved When limits have to be set to their endeavours it is a great deal to expect that they should always be relied on to decide wisely without some consultation on the best emphasis to be placed on the over all programme On the other side directors of clinical cancer research organisations are so rare as to be practically unheard of, and the anatomical specialisation within medicine has become so detailed and so widespread that there are few doctors attempting to survey the whole clinical cancer scene, let alone trying to keep contact with basic research as well There is, therefore, a sad lack of those with the interest and authority necessary for a proper discussion with the directors of the cancer research organisations to help them decide on the directions in which new effort might be made and from which unprofitable attempts might be withdrawn There seems to me to be an urgent need for more clinical cancer research workers, of a different class from those with complete academic freedom to follow their ideas who will concentrate on the neglected task of two way communication with the purpose of making research effective They are required to be familiar with the human problem so that the flow of ideas arising from it may reach the fundamental research workers and so that their discoveries may in turn have a channel to the ward It is of these middle men that I propose to speak—the links between basic cancer research and practice, the men with an insecure foot in both camps not always too well regarded by either but without whom freedom in fundamental research may become restricted with its viewpoint narrowed and the patient unlikely to reap the full benefit of the immense effort which is made

The Duties of the Middle-men

The first duty of these middle men is to be familiar with their subject, which is an extremely common disease process in man Sir Thomas Lewis said

> "When we investigate clinically some disease, or some manifestation of it, we may be seriously handicapped by circumstance, but we are possessed of the certain knowledge that what we study is precisely what we set out to study"

Their second duty is to find their way into research laboratories and staff rooms, to talk, to listen, to attend meetings, and to read review articles Their purpose here is to feel what is nowadays called the "climate of opinion" and to try to do two things The first is to feed in ideas gained in clinical practice, and the second to try to see the implications of new knowledge If they do this they will move amongst experts in every basic science and in every branch of medicine, each expert knowing so much more than they do about his own specialty that they may at times be in danger of feeling inferior instead of necessary If in some need of reassurance, they may repeat to themselves a few words spoken by Sir Francis Walshe which should give them comfort from both directions Sir Francis said

> "It is clear that experiment involves an even higher degree of abstraction than simple observation, for many more facts out of the total presenting are put in the discard, and this is why, perhaps, the experimental method, exclusively pursued, may prove somewhat narrowing to the mind, adverse to a philosophic generality of outlook, and to the free play of ideas ranging over the sum of presenting phenomena"

He also said in that same Harveian Oration

> "Some generality of understanding is the essence of civilised culture, and is a crying need in medicine and we must seek it earnestly if we are not to decline to the level of craftsmen and technicians"

Their third and main duty is to engage in research on their own account in the hospital ward—that laboratory nearest to their problems—in their own experimental laboratories, which do not need to be expensive or large, and in the collection, sorting, and analysis of detailed clinical observation, work which *does* need to be far more elaborately equipped and staffed than it has ever been before Their task here is to develop the ideas they will pass on to the basic research workers, to test hypotheses they have formed *from contact* with them, to clarify the problem to be tackled, and to assess the value of what is being *done about it* For my own part I would like to see a few outstanding physicians, clinical professors of medicine, engaged in this work, with their own beds and with access to those of their colleagues, and assisted by a sufficiency of clinical pathologists

A Middle-man's Point of View

Having stressed the need and said where I think the duties lie, I will try to sketch for you my view of the sort of philosophy which one of these middle-men might is thoughtful and thought provoking and should appeal to readers who are interested in methods of scientific inquiry and proof A chapter on medical and lay opinion illustrates amusingly the range of conclusions that may be drawn from the same evidence, but the general reader will probably be more interested to know the author's own verdict, which is "not proven"

---

* An address to the Plymouth Medical Society on Friday Dec 2, 1955

This is a good-tempered book by one who holds that "most smokers are not addicts, the pleasure of smoking is real " But it leaves an impression that the only serious objection to the present vast world consumption of tobacco is its possible relevance to cancer of the lung, and it does not therefore fulfil its claim to summarise present medical opinion and also to discuss the social implications of smoking

Infant Nutrition in the Tropics and Subtropics

D B JELLIFFE, M D, M R C P, D C H, D T M & H World Health Organisation Monograph Series no 29 Geneva 1955 Pp 237 25s

THE author, who is a W H O visiting professor of pædiatrics in Calcutta, has a wide experience of his subject, obtained in West Africa, Jamaica, and now in India He emphasises the importance of social anthropology as a background to pædiatric practice, and the need to learn the attitudes of mothers both to disease and feeding habits He is concerned with methods of instruction suitable for primitive or illiterate persons, and there is a good chapter on nutrition instruction in the maternal and child-health centre A large part of the monograph is taken up with an account, country by country, of infant-feeding practices

Dr Jelliffe is most interesting when writing from his experience he is far less apt with the literature, and the text is too frequently encumbered with long quotations from his 812 references The 24 figures and two coloured plates are of the high quality we have come to expect in United Nations publications The photographs taken in homes and hospitals leave a vivid impression of the tragedies of disease in childhood

---

Medical Research Mid Century Survey —This report of the American Foundation on Medical Research in the United States, which was discussed in a leader in our issue of Jan 7 (p 29), is published in this country by Messrs J & A Churchill, of London, at 5 guineas for the two volumes

An Atlas of Bone-Marrow Pathology (2nd ed London Heinemann 1955 Pp 85 30s)—That a second edition of Dr M C G Israëls's atlas has been called for shows that it has secured its place among the standard hæmatological works The text has undergone minor changes transitional or intermediate megaloblasts are now described and the plate illustrating the cytogenetics of erythroblasts is correspondingly modified, myeloid reticulosis and acute reticulum celled leukæmia are also described, and there is an illustration of metastatic cells from a gastric carcinoma All these are illustrated on a plate containing six new paintings The colour reproduction is excellent The atlas will be particularly useful to those who have to teach themselves hæmatology and who cannot refer continually to actual slides

Comparative Physiology of Reproduction (London Cambridge University Press 1955 Pp 253 50s)—No 4 of the memoirs of the Society of Endocrinology is based on a symposium held in July, 1954, at the University of Liverpool on the comparative endocrinology of vertebrates The memoir, which has been edited by Mr I Chester-Jones, PH.D and Dr Peter Eckstein, reviews reproductive patterns in fish, amphibia, reptiles, and mammals and goes on to describe the effects of sex hormones in groups of vertebrates Memoir no 5 (Pp 124 25s), on hormonal control of water and salt electrolyte metabolism in vertebrates, completes the record of the symposium

United States Dispensatory (25th ed Philadelphia J B Lippincott London Pitman Medical Publishing Co 1956 Pp 2139 £10) —The gestation period of elephants is lengthy, and it is not to be wondered that new editions of this enormous work of reference appear only every ten years The latest is the "biggest ever," and in preparing it Prof Arthur Osol, PH G, and Prof George Farrar, F A C P, have drawn information from the *British Pharmacopœia*, the *International Formulary*, *New and Non official Remedies*, and 25,000 issues of medical, pharmaceutical, biological, and chemical journals The book is bound in heavy buckram which looks as though it will stand up well to constant wear during the next ten years

Porphyrin Biosynthesis and Metabolism (London J & A Churchill 1955 Pp 308 30s) —The papers given at the symposium on this subject held by the Ciba Foundation in London in February, 1955, under the chairmanship of Prof C Rimington, F R S, have now been published The editors of the volume are Dr G E W Wolstenholme and Miss Elaine Millar, A H W C

New Inventions

DIATHERMY HÆMOSTATS FOR PROSTATECTOMY

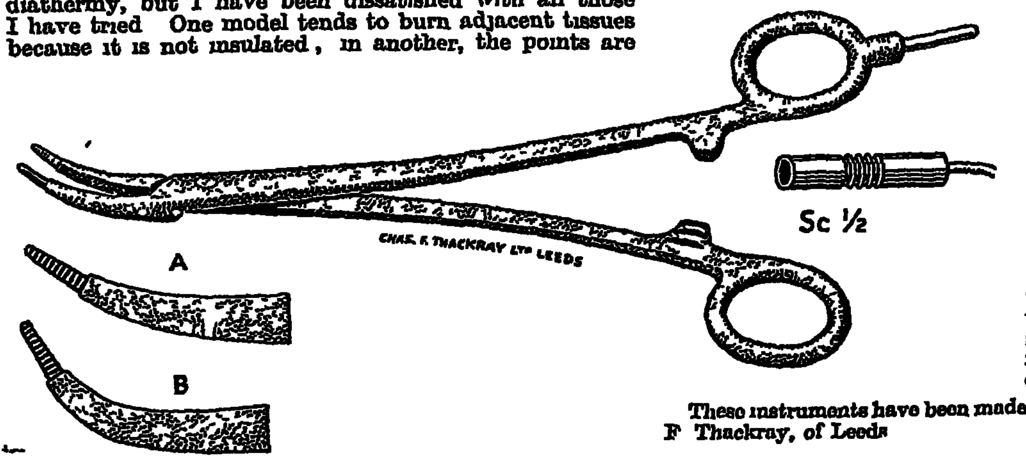
ESPECIALLY in those forms of prostatectomy in which the bladder is closed without drainage—e g, Millin's retropubic operation and the Wilson Hey procedure—efficient hæmostasis is essential Various artery forceps have been designed to obtain hæmostasis by diathermy, but I have been dissatisfied with all those I have tried One model tends to burn adjacent tissues because it is not insulated, in another, the points are too broad and blunt and the bite is therefore unnecessarily large Straight forceps are always difficult to use because the bleeding points in the prostatic bed are usually not on the floor but on the posterior and lateral walls

The hæmostats which I designed some time ago to overcome these difficulties have proved so satisfactory that they may be of interest to others—although I must emphasise that I claim no originality for them Their salient features are

1 The insulation is carried to within $^1/_4$ in of the extremity

2 The non insulated part is slender and "fines" down to a slightly blunted extremity

3 Two pairs are provided, both 9 in long The one in general use has only a slight curve The other, with its more pronounced curve, is used for bleeding points on the lateral wall of the prostatic cavity on the side of the operator, thus making it unnecessary for the surgeon to move to the opposite side during the operation



These instruments have been made for me by Messrs Charles F Thackray, of Leeds

echanisms, may at times be partly responsible for isorganised growth The long time that many of the citing factors take to act, the fact that promoting actors may shorten this time (one of the two perhaps y weakening local control) and that the shortest latent eriods are found with viruses—the only suspects which irectly introduce a new source of self-reproducing rotein into the cell—all seem to him to fit quite reason- bly into the picture Whether the control is overcome rom within the cell or from without, by increased eproductive activity or by relaxation of those influences hich hold its reproductive urge at bay, or through some ombination of the two, the result in terms of changed ehaviour pattern or of the cancer process is likely to e the same No special intracellular evil seems necessary o explain this process, though several different ones ay each play their part at times, when such intra- ellular changes and weakening of extracellular controls ccur together they are likely to be more effective than ither is alone This view limits but does not deny he *findings of research workers who have adhered to the* irus theory, the mutation theory, or other intracellular iews, indeed, it seems to make possible the reconciliation of much of their work which appeared to be in onflict

Perhaps then, thinks this man of ours upon his bridge, the idea of a special evil always present within every cancer cell, so diligently sought on the one side and so relentlessly pursued on the other, may be a myth Since belief in its existence has dominated cancer thought for so long without much profit to the patient he wonders what would happen if more people seriously considered once again the possibility that there may be substance in the hypothesis that the cancer cell is basically normal and that what goes wrong is essentially due to interference with organisation It is organisation which appears to be the unstable marvel of human existence——not disorganisation, which is merely its inevitable accompaniment A similar permissive view of cancer has been held by many, but there would seem to be more reason for holding it today than ever before Sir William Savory, in the third Bradshaw Lecture in 1884, said

> "Before we shall ever be able to answer the question, why or how do tumours form? it seems to me we must be able to solve the problem of normal growth and development and to answer the question why or how it is that these continue up to a certain point and then suddenly cease"

The great questions of orderly development and maintenance are better understood than they were then but still seem no less fundamental to the problems of disorderly development and decay The wonder is not that we should be faced with disorganised growth or cancer, but that organised growth should occur at all and that disorganisation should often be so delayed that many people are preserved long after they have ceased to be biologically useful

In multicellular organisms with sexual reproduction, only those cells which achieve physiological isolation after fertilisation but before differentiation and which are situated in a favourable environment are able to produce whole adult organisms whether as twins or other multiples Those which become isolated after some differentiation has occurred though no longer both totipotential and suitably placed, may still be pleuripotential and able to establish some imperfect organisation of their own in their attempt to fulfil their inheritance If already specialised and type specific they may, when isolated and dedifferentiated, produce a mass of primitive cells only faintly resembling their tissue of origin, being more like the cells from which that tissue was derived Undifferentiated tumours arising in many different tissues are notoriously alike The only cells which never seem to escape from control are those fixed postmitotic cells which have differentiated away their whole inheritance, leaving themselves no other possibility of self expression—one example of which is to be found in the lens of the eye

Seen in this light, cancer appears as a name applied loosely to the most disorganised end of an ill defined group of disorders of growth which are due to an inevitable breakdown of some part of that complicated organisation of the body which is able to build it up and to maintain it for a while as a functioning whole The cancer cell is then seen as a normal cell which, through physiological isolation, has partially escaped from the body's control mechanisms, undergone some dedifferentiation, and is trying under more or less difficult circumstances to express its natural potentialities The manifestations of cancer depend on the one hand on the degree to which control is overcome, the amount of dedifferentiation achieved and the possibilities for developmental expression remaining to the cells affected, and on the other on the sites at which loss of control *has occurred and their extent, the favourability of the* environment in these regions for growth, the distribution throughout the body of the cells affected, and the opportunities for dissemination The causes of cancer appear as any of those many conditions which lead to the physiological isolation of cells from their fellows in any complicated organism These multiple causes are seen to be in two main groups those raising cell activity above that of its control and those lowering the controls The first group contains most of the irritant, inciting, carcinogenic factors, all those injuries which demand repeated attempts at regeneration, recurrent local hormone stimulation, and any of the intracellular changes which may increase cellular growth potential The second contains the poorly understood process of ageing, those nervous and metabolic gradients which largely determine and maintain our growth and form, perhaps some of the cancer-promoting agents which may affect these local control mechanisms, and the general hormone system of diffusable control of homologous tissues and of tissues related in some common function throughout the body

"The cure of cancer" becomes a meaningless phrase while the cure of individual patients with cancers at special sites has long been an established fact The future is seen to lie with more efficient prevention or postponement of tissue disorganisation, with better removal or destruction of some disorganised tissues, and with renewed attempts at re establishment of control, knowing that these may all be successful in individual tissues of individual patients but not in any generality A final, complete solution of this problem is seen to be impossible, since it is part of the nature of complicated organisms that they cannot maintain their organisation indefinitely Only an isolated unicellular organism in a boundless, favourable environment is immortal and eternally expressing its inherent ability for endless self-reproduction Evolution is not compatible with immortality, it requires complexity and organisation for expression and death for progress

Fundamental Cancer Research

Having considered his point of view, the middle man may then look towards the basic research workers Individually they seem much like scientists in any field, but collectively they appear to differ from most other groups in that their work is not centred around a single basic discipline but around an ill-defined disease process of which most of them have no first hand knowledge in the human patient at all They are clearly not inhibited into inaction by a long acquaintance with the march of this illusive disease, they have been trained in their respective scientific fields to expect to be able to find answers to most questions if they work long and hard enough, and for the most part they seem eager and

Heat, Salt, and Water

As "payment" for the advantages of a highly developed heat-regulating mechanism, man must constantly make good the salt and water lost in the sweat In the laboratory, sweat losses up to 8 litres in four hours have been recorded, but the high temperatures and work-rates involved cannot be long sustained, and the total lost in twenty-four hours in hot countries is probably rarely more than 10 litres The salt content of sweat is so variable that the range of salt loss is hard to estimate Moreover, there is considerable variation in the response of the individual exposed repeatedly or continuously to heat, and it has often been shown that a degree of acclimatisation develops The features of acclimatisation are (1) an increase in the rate of sweating, (2) a lower pulse-rate, and (3) a lower body-temperature, as compared with the initial response to hot conditions, and these changes are accompanied by an increasing sense of well-being Different workers have given different times for the development of acclimatisation, but five to fifteen days covers most estimates, provided the subjects are exposed to fairly severe conditions and also do physical work of moderate intensity[1 2] The corollary to these findings is that the tolerance-time for severe conditions increases steadily during acclimatisation These changes in sweat-rate, body-temperature, and heart-rate do not continue indefinitely, after about fifteen days there is little further change, except that the sweat-rate may gradually decline over a period of weeks or months[3]

These findings form the basis for assessing water and salt requirement in conditions of heat ADOLPH[4] has shown that man cannot adapt himself to a diminished water-supply Furthermore, with one possible exception (the "free circulating water" of LADELL[5]), man cannot carry a reserve of water in the body the drinking of extra water, before exposure to conditions of water loss, is useless because the excess water simply induces a diuresis ADOLPH has also pointed out that thirst is a poor guide to water requirements, and severe dehydration can develop with an adequate water-supply available, when intakes of about 10 litres per day are needed It might seem that with a diminished water intake a high sweat-rate would fall, and so lead to a rise in body-temperature, but it has been claimed that moderate water deficiency does not significantly alter the sweat-rate[6 7] This problem has been re-examined by LADELL,[5] who has analysed data from experiments carried out some ten years ago by the Medical Research Council team at the National Hospital for Nervous Diseases, Queen Square, London During short exposures to severe heat he found that abstention from water had no effect on the sweat-rate until the water debt exceeded 2 5 litres This point has considerable academic as well as practical importance The effects of acclimatisation and the considerable differences from person to person make the design of climatic experiments far from simple In conducting climatic experiments in hot environments, when the subjects are sweating freely, should they be allowed to drink at will, or should water be replaced strictly according to the sweat loss? Or should there be a fixed ration for them all? Clearly, it would be easier to plan experiments of this kind if water intake had in fact no influence on sweat-rate The problem was carefully investigated by ELLIS and his colleagues in the M R C team at the Royal Naval Tropical Research Unit at Singapore[8] They showed, quite clearly, that the amount of sweat secreted varied with the amount of water drunk It seems that the reason for the disagreement between these and earlier results was that ELLIS and his co-workers were able, thanks to the work at Queen Square and the experience of the research-workers there, to control more exactly the conditions for their experiments

LADELL[5] has also put forward the view that there is a volume of "free circulating water" which is approximately 2–2 5 litres, and that until this volume has been lost bodily function continues unimpaired This view is in accordance with his studies of water deprivation in temperate surroundings, where he found little change in the volume of urine secreted until twenty-four hours after water intake ceased In acclimatisation to heat this "free-water volume" may increase BASS et al,[9] after a very detailed study of acclimatisation in man, conclude that an important feature was an expansion of the extracellular fluid volume in the first few days of exposure to heat They believe that this expansion (in which the blood-plasma was included) was largely responsible for the greater cardiovascular efficiency which they regard as the essential feature of adaptation to heat We may provisionally conclude that water intake has a small but definite effect on the sweat rate, although further work is needed on a wider range of environments and water intakes

The question of salt requirement is equally important At present we know that the salt content of the sweat is determined by the salt intake, by the degree of acclimatisation, and by the severity and the duration of the exposure to heat MCCANCE[10] and others have shown that the commonly observed decline in the salt content of sweat with continued exposure to heat can be due to inadequate salt intake The studies of BASS et al, however, indicate that with adequate salt replacement salt is retained during the first few days of heat exposure, and, in their view, the retained salt is needed for the increase in the extracellular fluid volume Once this has been achieved, the kidneys excrete more or less salt, as required to maintain a balance Calculations of sodium-chloride balances depend for their accuracy on the techniques used to take a sample of sweat A convenient and widely used method is to collect sweat in an arm bag By this method, LADELL has produced a chart from which intracellular fluid volume can be calculated from the salt and water balances

having posed their question they can only go on doing their best until some magic answer arrives It seems that this is a situation which needs breaking up, and that nothing is so likely to do it as to persuade doctors to take a new and controversial view of the basic assumptions they have made

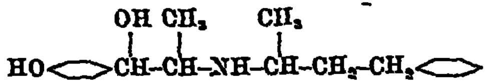
The effects on physicians of holding this common, simple, and perhaps unfounded view have been many One tendency has been that whenever they get into difficulties with classification they are apt to adjust their definition So wedded are they to fatality that a patient who lives, especially if treated by a method they do not themselves practise, is readily accepted as having had some other disease until he dies, but then cancer is still likely to be written on his death certificate however long he may have been symptom-free When to this attitude is added a knowledge of the overriding importance of the nature of the tumour to any result which can be obtained by any treatment, a hopeless view of excellent work may further depress enthusiasm Eagerness and confidence too easily pass to the thoughtless and the quacks To many, however, a growing knowledge of the variety of behaviour exhibited by tumours under different circumstances is bringing healthy doubt as to the validity of the old simple thesis while the obvious advances in diagnosis, and in surgery and radiotherapy, bring new enthusiasm and hope The growing interest in organisation and control that has followed the demonstration that the whole course of the disease can be influenced by alteration in hormone balance is adding impetus to this changing conception The growing recognition of the importance of biological predeterminism in human cancer, whereby the stage is set for the behaviour pattern which is to follow by the degree of dedifferentiation and the mitotic-rate established, is helping in the better selection of treatment method and leading to a sounder understanding both of what is possible and of what has really been achieved The slow penetration of this view through the general body of medicine seems to be due chiefly to the fact that so few people are primarily concerned, and to the combination of fatalistic and miraculous frames of mind which have flourished amongst doctors far too long What the middle-man wants from clinicians are ideas born of long experience, minds receptive to implications derived from basic research, and an unbiased attitude which makes all possible forms of aid available to every patient according to his need and not according to the skills of the first specialist he sees

As the man on the bridge looks into the future he wonders if any real appreciation of the cancer problem as a natural phenomenon, stripped of shame, to be accepted, coped with, but never conquered, will come easily It may well be the general public that is most ready to accept it and to find in it relief from fear The medical effort may become more firmly concentrated on prevention and postponement of disorganisation The initiative may pass into their hands once more so that they see this problem again as primarily their own job and not as somebody else's, as a job not really any more difficult because it can never be finally disposed of one of great importance in medicine and very well worth doing So much of value is already being done, its worth is underestimated only because it does not seem to provide a simple answer in terms of survival to all the impossible questions put A doctor's job is to continue to learn, to comfort, encourage, relieve, and to cure when he can, it is no part of his business to become a mere disinterested spectator waiting for a miracle to occur against the whole force of Nature The cancer problem is ours, and we must see to it that more people actively engage in the clinical research work so necessary if the sensible and possible advances are to flow from the application of new knowledge

DILATAL IN THE TREATMENT OF INTERMITTENT CLAUDICATION IN THE CALF MUSCLES

D N WALDER
M D Brist, F R C S, F R C S E
SENIOR LECTURER IN EXPERIMENTAL SURGERY IN THE UNIVERSITY OF DURHAM

'DILATAL' is a recently introduced drug which is claimed to increase muscle circulation It was synthesised by Kulz and Schneider (1950) from an adrenaline-like basal substance, parahydroxy ephedrine, to which by substitution a lengthy side chain had been added to give phenyl-iso butyl nor-parahydroxy ephedrine



$$\mathrm{HO{-}C_6H_4{-}CH(OH){-}CH(CH_3){-}NH{-}CH(CH_3){-}CH_2{-}CH_2{-}C_6H_5}$$

It is known that adrenaline given by continuous infusion intravenously to man increases the resting muscle blood-flow (Allen et al 1946) Kulz and Schneider were looking for a substance which would have this effect without the side effects of adrenaline and would be active when given by mouth

Wiemers (1951) showed that dilatal 0 1 mg per kg of body-weight given intravenously to anæsthetised dogs and cats lowered the blood-pressure and moderately raised the pulse and respiration rates The coronary circulation was increased, but there was only a slight change in cardiac output Plethysmography of the hind limbs of dogs showed an increase in blood flow of 200–300%, which lasted for 10–15 minutes The vasodilator effect was shown to be greater in the muscle vessels than in the skin vessels

If such an effect could be paralleled in man, dilatal might be of value in treating those forms of peripheral vascular disease affecting muscle blood-flow and associated with intermittent claudication

Dilatal has been extensively used clinically in Germany for many conditions, but few of the trials reported included a critical examination of its effect on muscle blood-flow Ostwald (1950) states that "vigorous stimulation of muscle circulation was observed" but gives no figures Hensel et al (1955), in America, using the calorimetersende to measure muscle blood flow, state that in 8 of 10 healthy persons the blood flow increased up to 250% of the resting value, and the increase lasted for 50 minutes when dilatal was infused intravenously for 10 minutes In England Riddell et al (1954) studied the effect of dilatal 5 mg per kg of body-weight given by mouth to healthy adults and noted, among other changes, a transient increase in flow, measured by plethysmography in the calf and foot, to twice its normal resting value for about 10 minutes and a slightly greater increase in the blood flow of the hand From these observations they concluded that the main effect of dilatal was on the skin vessels rather than the muscle vessels It is doubtful whether their results are statistically significant

The published evidence does not provide a satisfactory answer to the questions whether muscle blood-flow in man is enhanced to any significant extent by dilatal or whether patients with intermittent claudication can benefit from it It was therefore decided to submit it to a trial by clinical experiment

Clinical Trial

After consultation with the makers it was decided to give a dose of 2 5 mg (one tablet) every 2 hours (preferably after meals) during the day, starting at 8 A M and finishing at 6 P M A course of tablets lasting 8–9 weeks was given

52 patients were collected from the hospital outpatient department The criteria used in their selection was that

And how do people spend their leisure? There is very little information, though plenty of baseless belief, on what different sorts of people of different ages do with their time, and how this is changing with the coming of television, for instance On this, as on a great deal of work psychology and sociology, the labour of research is waiting to be done But the doctor's task, as champion of the individual's welfare, is above all to remind the planners of the new industrial age of the diversity of individuals Automation will not bring happiness with its riches unless it is planned for men

Annotations

TUBERCULOSIS THEN AND NOW

THREE medical journals in this country are concerned exclusively with diseases of the chest and tuberculosis The youngest of them, *Thorax*, was founded in 1946, *Tubercle* started 27 years earlier, in 1919, and the oldest, the *British Journal of Tuberculosis and Diseases of the Chest*, published its first number 49 years ago, in January, 1907 The special number marking its golden jubilee has a series of articles under the general title "Fifty Years On—Then and Now," and its impressive record of progress is summed up in an editorial which wisely draws attention to the present need to define the limits of the specialty in radically altered and rapidly changing conditions "The attainment of a comprehensive chest service which will include respiratory tuberculosis and all other chest disease *integrated with other branches of medicine* must surely," the journal says, "be our aim, with prevention, diagnosis, treatment and after care, including rehabilitation, coordinated as one continuous process"

At first sight few will dispute this policy, but it would perhaps be wise to examine its implications more fully before they become accepted as self evident The study of diseases of the chest is an established specialty and it should continue to be one the subject, even without pulmonary tuberculosis, is quite large enough to justify a special compartment But it cannot be assumed from this alone that a "comprehensive chest service" is desirable Neurology is an accepted specialty, but a comprehensive neurology service has, as far as we know, not been suggested Is there a place for a comprehensive heart service or skin service? The idea of a chest service does not appear incongruous, because it develops from an established and familiar institution—the tuberculosis service But it is hard to believe that diseases of the respiratory system, other than tuberculosis, differ so much in social significance that they need a service that cannot be provided by the general hospital If, as is hoped, the prevalence of tuberculosis decreases to such an extent that the resources of the chest clinics and chest hospitals become inadequately employed, it may be expedient to use them for purposes other than the prevention and treatment of tuberculosis But it may not necessarily be right to do so Before considering how chest clinics can best be employed, it might be profitable, though unpopular, to ask whether they should continue to exist at all, and whether the administrative stroke that attempted to turn 'tuberculosis dispensaries" into "chest clinics" and "tuberculosis officers" into "chest physicians" was indeed a wise decision The experience of the past fifty years has demonstrated the value of a comprehensive tuberculosis service, but those who advocate an equally comprehensive chest service must do more than rest their case on tuberculosis then and now

PENICILLIN V

VARIOUS penicillins with different properties have been produced by changing the strain of the fungus, the conditions of growth, and the composition of the medium So far, penicillin G has been the most widely used A new type of penicillin, penicillin V, or phenoxymethyl penicillin, has been produced by biosynthesis by growing *Penicillium chrysogenum* Q176 in a culture medium containing a special type of nutrient[1] Being an acid and acid resistant, penicillin V passes through the stomach unchanged, unlike penicillin G, which is partially inactivated by acid, and is largely destroyed by the acid gastric juice if taken by mouth[2,3] Oral absorption of penicillin G is variable and much larger doses must be given by mouth than by injection Penicillin V is stable as the free acid, and, unlike the other penicillins, need not be prepared as a metallic or organic salt It is dissolved and absorbed unchanged in the alkaline medium of the small intestine, and is therefore eminently suitable for oral administration Broadly speaking, its antibacterial spectrum is identical with that of penicillin G, but it is said to be 60% more active than the latter against *Staphylococcus aureus*[3] The two penicillins also differ slightly in their activity against *Micrococcus pyogenes* Because of slight quantitative differences in their action on the test organisms in biological assay, the dose of penicillin V is best assessed by weight in mg and not in units 60 mg of penicillin V is equivalent to 100,000 units of penicillin G by chemical assay

After penicillin V has been given by mouth, the blood levels are higher and more sustained than those produced by an equivalent dose of penicillin G[1] An oral dose of 120 mg (200,000 units) of penicillin V gives detectable blood levels six hours after administration, although the level declines after four hours[5] If this quantity of penicillin G is given orally, the blood level is approaching zero after six hours[6] The recommended dose of penicillin V is 120–240 mg every four hours round the clock, but for convenience the last night dose can be doubled to avoid awakening the patient in the night About 25% of an oral dose of penicillin V is excreted in the urine[7] It is more sensitive to penicillinase than penicillin G, and therefore any that is unabsorbed when taken by mouth is destroyed in the lower part of the gut by organisms producing penicillinase Like penicillin G, penicillin V does not readily penetrate the blood-brain barrier in normal subjects It is possible, however, that it may traverse it if the meninges are inflamed, just as penicillin G does Therapeutically effective amounts of penicillin V have been found to diffuse into the pleural and peritoneal cavities, and to be excreted into the bile[8]

In the treatment of mild to moderate infections due to susceptible organisms, 120–240 mg of penicillin V every four hours has been found effective If the infection is severe, it may be necessary to use a higher dosage (e g, 480 mg), and to give it more frequently[6] Reactions and sensitivity seem just as likely with this new penicillin as with penicillin G Gastro intestinal irritation with loose stools, no doubt due to altering the balance of the intestinal flora, has been reported[6,9] Preliminary reports with penicillin V in this country have been encourag

The work done during the exercise was calculated in the llowing way The patient did the exercise of raising mself up and down on his toes standing with a light ard resting on his head This board was arranged that it was pushed vertically up by the patient's head ery time he raised himself on his toes The board llowed the downward movement of the patient's head he lowered himself The movements of the board were corded on a kymograph smoked paper This provided permanent record of the height to which the patient used himself each time he went up on his toes By ultiplying the patient's weight (in lb) by the total f all the individual heights to which he raised himself in ft) the total work done can be calculated (ft -lb)

ABLE I—PATIENT'S OWN ESTIMATE OF IMPROVEMENT AFTER TREATMENT

Improvement in walking distance (yards)	Patients taking dilatal	Patients taking placebo
>300	7	2
151–300	3	1
0–150	8	8
N C	8	12
−0–150	0	1
Total	26	24

t = 2·71 P = <0·01

Results of Clinical Trial

Patient's Estimate of Improvement after Treatment

Table I shows that, of those patients who felt they had derived some benefit from the course of tablets, more came from the group who had been on dilatal than from the group who had been on the placebo A statistical analysis based on the patient's estimate of his increased walking distance after his course of tablets showed a sig[illegible]cant improvement in those who had taken dilatal [illegible]ared with those who had been given the placebo [illegible] 2·71 P < 0·01)

Measured Improvement Following Treatment

(1) The amount of work possible (ft -lb)
(2) The duration of work possible (min)

In neither of these factors did the patients who had dilatal for 8 weeks improve to such an extent as to make the results significantly different from those of the patients who received placebo tablets When the two factors are plotted as a scattergram—one for those patients who received dilatal and one for those patients who received placebo tablets—there is a remarkable similarity in the distribution of the points (figs 2 and 3)

(3) The rate of doing work (ft -lb per min)
(4) The resting blood-flow (ml per 100 g per min)
(5) The greatest post exercise blood-flow (ml per 100 g per min)

There was no significant difference between the results obtained after treatment by the patients on dilatal and those on placebo tablets either in the improvement of the rate of doing work (t = 0·66, P > 0·5), improvement of resting blood-flow (t = 0·95, P > 0·3), or improvement in greatest post-exercise blood flow (t = 0·33, P > 0·9)

(6) Duration of post-exercise hyperæmia

If dilatal produces a more efficient circulation in the calf muscles, it might be expected that the post-exercise hyperæmia would not last so long in the patients on dilatal as in those receiving placebo tablets In fact, there was no significant statistical evidence to indicate that dilatal had materially affected this factor (t = 0·21, P = > 0·8)

TABLE II—INFLUENCE OF PREVIOUS TREATMENT
Patient's own estimate of improvement

Previous treatment	Patients taking dilatal		Patients taking placebo	
	Total	Improved	Total	Improved
None	5	5	4	2
Sympathectomy	14	10	13	5
Tolazoline	7	3	7	4

TABLE III—INFLUENCE OF PREVIOUS TREATMENT
(Number of legs showing improvement (amount of work possible) after treatment

Previous treatment	Patients taking dilatal		Patients taking placebo	
	Total	Improved	Total	Improved
None	9	6	8	2
Sympathectomy	28	14	26	18
Tolazoline	14	6	14	7

(7) The influence of the previous treatment

When the results are examined from the point of view of the patients' treatment previous to the trial (tables II and III), it is seen that the best results with dilatal were obtained in those patients who had received no previous treatment The patients who had been treated by sympathectomy benefited more than those who had received a previous course of tolazoline No statistical analysis of these results has been attempted because the number of individuals in each group is so small

TABLE IV—EFFECT OF DILATAL ON RESTING BLOOD FLOW OF RIGHT AND LEFT CALVES OF PATIENTS WITH INTERMITTENT CLAUDICATION

Case no	Resting blood flow before dilatal (ml per 100 g per min)	Dose of dilatal (mg)	Peak resting blood flow after dilatal (ml per 100 g per min)	Increase (%)	Duration of blood flow above pre-dilatal level (min)
1	R 0·6	2·5 (oral)	R 2·8	350	50
	L 1·0		L 1·7	70	15
2	R 1·4	„	R 1·1	0	0

Results of Acute Experiments

Some patients showed a transient improvement in resting blood flow when given dilatal The peak improvement in one case was 350% Many patients, however, showed no increase in blood-flow after a course of dilatal (table IV)

Discussion

Perhaps one of the most interesting points brought out by this trial is the spontaneous improvement of some patients on the placebo tablets Figs 2 and 3 show that 22 of 48 (45%) of the legs of the patients receiving placebo tablets were improved at the end of their course in that the patients were able to do more work in the same time or for a longer time, whereas 22 of 51 (43%) of the legs of patients taking dilatal were improved This observation emphasises the importance of having a control series of patients when clinically testing drugs of this type in a condition such as intermittent claudicafull anticonvulsant potency after the mice had undergone bilateral nephrectomy The anticonvulsant property of the sulphonamides seemed to be related to carbonic anhydrase inhibition, but it was evidently not dependent on the production of metabolic acidosis In fact further experiments showed that when acidosis was induced in mice by administration of ammonium chloride, *only a very slight degree of protection against* convulsions was conferred Millichap et al next turned their attention to carbonic anhydrase in the brain They found that after administration of equivalent amounts of the two drugs sulphanilamide was present in the brain in a concentration fifty times greater than that of acetazolamide Since acetazolamide was one hundred times more powerful an inhibitor of carbonic anhydrase, it was evident that after equal doses acetazolamide would exert twice the degree of enzyme inhibition This corresponded with the observation that acetazolamide was twice as effective as sulphanilamide in the prevention of seizures Moreover, the two drugs had their strongest anticonvulsant action at a time when the inhibition of carbonic anhydrase was greatest

It is not yet clear in what way inhibition of carbonic anhydrase in the brain prevents convulsions Not all anticonvulsant drugs act in this way, since phenobarbitone, phenytoin, and troxidone do not inhibit carbonic anhydrase[27] Inhibition of carbonic anhydrase leads to the accumulation of carbon dioxide at the nerve cell membrane, and the resulting decrease in the velocity of conduction of impulses may be related to the lowered susceptibility to convulsions Further research is proceeding on this subject, and meanwhile it has again been demonstrated that acetazolamide is a valuable tool in the study of fundamental cellular mechanisms

SALMONELLÆ OFF THEIR BEAT

DURING a period of three months salmonella infections were acquired by 5 hospital patients Investigating these cases, Kunz and Ouchterlony[28] found the source of the organisms in a previously unsuspected food product —namely, dried brewers' yeast Each of the 5 patients had been fed by stomach-tube In the wards and diet kitchens concerned, none of the staff were carriers of salmonellæ, and attention was turned to the tube-feeds At the time of the infections the preparation of the tube-feeds did not include boiling or heating of the ingredients or of the finished product Dried yeast and spray dried milk powder were common to all the feeds given to the infected patients, and (rather unexpectedly) the yeast it was that showed the presence of salmonellæ on culture

To culture salmonellæ from the yeast it was necessary to examine large samples, each of from 50 to 100 g, and to leave them in contact with 200 ml of water, saline, or broth for from six to twenty-four hours at 30–37°C before culturing Several 1 or 2 ml aliquots of the suspension, each in 10 ml of selenite and of tetrathionate broth, were taken for culture and thereafter the ordinary procedure was followed Examination of small samples without preliminary "hydration" gave negative cultures from batches of yeast subsequently proved to contain salmonellæ The way in which the yeast became infected during manufacture was of interest because yeast is only one of many dried foods all of which may be subject to the same hazards Salmonellæ were not found either in the equipment or in yeast from the culture tanks, separators, holding tanks, drying drums, or intermediate conveyors It was only during the final stages of milling, screening, and packing that salmonellæ were occasionally found Finally, it was established that the bacteria were being introduced into the factory through a ventilating duct, and when the incoming air was filtered the contamination ceased It is very likely, although not proven, that the ultimate source of the salmonellæ was the excreta of animal This speculation is of particular interest in view of the report by Rohde[29] of an outbreak of salmonella infection in *Hamburg, in 1954,* which was traced to pastry, the original source of the infection being apparently wheaten flour from a mill heavily infested with rats and mice

A third unexpected vehicle for the transmission of salmonellæ was recently discovered in Melbourne by Wilson and Mackenzie[30] who, investigating an outbreak of typhoid fever, found a variety of salmonella species, including *Salmonella typhi*, in desiccated coconut produced under very primitive conditions in Papua and imported into Australia

Knowledge of these unexpected sources of salmonellæ may help and even stimulate day-to day inquiries into food-poisoning incidents But the main burden of the problem of food-poisoning lies in discovering how to control the familiar sources of infection One useful lead in this connection is the evidence produced by Anderson and Stone[31] that spray dried milk manufactured in warm weather, especially near the end of a day when the equipment needs cleaning, may actually contain not only abundant staphylococci but, in all probability, their pre formed toxin also, which is well preserved by drying

A useful and comprehensive survey of many other and more familiar problems of food-poisoning was given by a group of distinguished contributors to a symposium on Food Microbiology and Public Health which was held at Cambridge last July by the Society for Applied Bacteriology[32]

THE USE OF AN AMBULANCE

IT is reported[33] that an ambulance service refused to carry a doctor, a nurse, and drugs to help a patient who had collapsed in his home The reason given was that an ambulance is provided, according to the regulations, "to convey patients where necessary," and that it is not the duty of the ambulance service to convey doctors and drugs A neighbouring ambulance service undertook the task, apparently on the principle that it is better to do what appears necessary, and to make inquiries afterwards It may well be that a private car or a taxi could have been used, and this was pointed out at the time, but many people will be left with the feeling that regulations were interpreted too strictly on this occasion Of course the organisation which sticks most carefully to its regulations is most likely to seem efficient in the eyes of authority, but it will rarely be able to react quickly to the unexpected situation for which no regulations provide Those who declined to respond to this call for an ambulance may say that "urgent" calls are often exaggerated and sometimes unnecessary, and that speed is seldom as important under these circumstances as many people believe Certainly this particular patient died in a few hours, and there was probably nothing more that could have been done to save him But that is hardly the point there should be no doubt in anybody's mind that the utmost has been done for a patient, and the facts reported in this case will not dispel all doubts ifficult to conceive that a circulating toxin or metabolite should cease to function with amputation of the lung.

Wyburn Mason (1948), however, stated that in two cases of hypertrophic osteoarthropathy that were known to him mere ligature of the pulmonary artery without removal of the lung had the same immediate effect in relieving arthropathy as excision. This might be assumed to support the theory of a circulating toxin arising from the neoplasm. Hansen (1952) described the association of arthralgia with bronchial carcinoma in four cases of his own. In three of these resection led to complete relief of symptoms due to osteoarthropathy. In the fourth case the operation was abandoned after extensive dissection of the hilum. Although no vessels were tied the pain disappeared as in the other three cases, and he speculated as to whether hilar neurectomy had brought about this result.

It has long seemed evident to me that only a neural reflex could explain the abrupt and consistent cessation of pain; and in the cases mentioned by Wyburn Mason (1948) I believe that the arrest of symptoms was due, not to the ligature of the pulmonary artery, but to the fact that, as in Hansen's case, clearance of the hilum with severance of the nerve-fibres entering it, was first performed.

Operation

In the pursuance of this belief I have now performed a number of operations, mostly on patients with inoperable bronchial carcinomas accompanied by hypertrophic osteoarthropathy.

In several patients I performed as complete a hilar clearance as possible, dividing the pleural investment and all the fibres of the vagus or sympathetic entering the root of the lung. In these cases the joint pains were relieved as effectively as in other cases treated by pulmonary resection. In two patients who had clubbing and arthralgia exploratory thoracotomy alone had no effect.

As the vagus branches to the lung are easily recognised and isolated, I next tried division of these alone avoiding all interference with the rest of the hilum.

Case-reports

Case 1.—A man, aged 53, in February, 1953, noticed that his feet and legs had become swollen and painful, and he had to give up his work on this account. He was admitted to hospital where his knees also swelled and became painful. Pain also developed in arms and wrists and was so severe that it kept him awake at night.

Examination.—Clubbing of fingers and toes. Effusions in both knees and elbows with limitation of movement and swelling of interphalangeal joints. Tenderness of tibiæ and humeri. Radiography showed new subperiosteal bone formation on the right femur, and a mass at the right hilum.

Operation (May 11).—Right thoracotomy: an inoperable carcinoma was present at the hilum accompanied by numerous carcinomatous mediastinal glands. All the branches of the vagus entering the hilum were identified and cut. Biopsy showed polygonal cell bronchial carcinoma.

Postoperative Course.—Immediately after operation all joint pain was abolished and limb movements at once greatly improved. On Nov. 20 his doctor reported: "He is going downhill and losing weight, but the pains for which he had his neurectomy have never recurred." The patient died on Feb. 16, 1954, without having had any recurrence of his joint symptoms.

Case 2.—A man, aged 49, in January, 1953, first noticed swelling of ankles, wrists, and hands. February: onset of aching pain in knees and elbows which kept him awake; movement of these joints greatly limited. March: pains worse.

Examination.—Gross clubbing of fingers and toes. Swelling of wrists and ankles. Radiography showed typical and extensive hypertrophic pulmonary osteoarthropathy of long bones; carcinoma in the upper lobe of the left lung.

Operation (April 13).—Left thoracotomy: irremovable carcinoma arising in the upper lobe, extending into the hilum, and involving the arch of the aorta. The branches of the vagus entering the hilum were alone cut and the chest closed.

Postoperative Course.—All joint pains were dramatically relieved, and within twenty four hours the patient could flex his knees and ankles for the first time in weeks. On July 23 his doctor reported: "Going rapidly downhill, but no pain or swelling of joints."

Case 3.—A man, aged 68, was admitted to hospital on March 24, 1955, with cardiac infarction and was found to have an abnormal opacity in the lower lobe of his right lung. Squamous carcinoma cells present in sputum. Refused operation. In October he began to have rheumatism-like pains in elbows, wrists, ankles and knees, gradually becoming more severe and causing him considerable distress.

Examination.—Complaining bitterly of joint pains. Severe clubbing of fingers. Some swelling of affected joints. Radiography showed new subperiosteal bone on shafts of long bones, characteristic of hypertrophic osteoarthropathy.

Operation (Sept. 19).—Right thoracotomy: mass of neoplasm in right lower lobe; secondary deposits on surface of upper and middle lobes and on parietal pleura. The hilum of the lung was not touched but the right vagus was picked up high on the mediastinum above the vena azygos and cut.

Postoperative Course.—The following day all joint pains had vanished and they have never recurred. The swelling of joints subsided within a day or two. The patient was completely relieved of skeletal symptoms.

Case 4.—A man, aged 45, in August, 1955, began to have swelling and later pain in the ankles. A month later the knees were swollen and painful; and after a further month the wrists were swollen and elbows and fingers were stiff and painful.

Examination.—Gross clubbing of fingers and toes. Gross effusions in both elbows, knees, and ankles. Radiography showed typical hypertrophic osteoarthropathy of all the long bones; small opacity in the upper lobe of the left lung. Squamous cells were present in the sputum. The patient agreed to a two stage operation.

First Operation (Nov. 23).—A left intercostal incision was made and the presence of an operable carcinoma in the upper lobe of the left lung confirmed. Without disturbing any of the hilar structures the left vagus was picked up just distal to its recurrent laryngeal branch and cut; the chest was closed.

Postoperative Course.—The following morning the patient was asked if he felt any different. "Goodness me, yes," he said, "all my pains are gone; and look—I can bend my knees for the first time in weeks!" Within forty eight hours the effusions in his knees and ankles had almost disappeared, and neither these nor the joint pains have recurred.

Second Operation (Nov. 30).—The wound was reopened and a left upper lobectomy carried out. The tumour was a squamous cell carcinoma and there was no spread to regional glands. The second operation made no difference to the patient, all of whose joint symptoms had already disappeared in the week after vagotomy and before resection of the lung.

Case 5.—A man, aged 59, six months before admission, began to have aching pain in his knees and ankles and later in the wrists and elbows. The pains persisted until operation and were sufficiently severe to keep him awake at night. Some time after their onset he began to cough and to lose weight.

On examination his fingers were clubbed and there were small effusions in both knees. Radiographs of the chest showed collapse of the middle and lower lobes of the right lung, and bronchoscopy confirmed the presence of an inoperable squamous celled carcinoma of the bronchus. There was well marked new subperiosteal bone formation down the shafts of radius, ulna, tibia, and fibula on both sides of the body.

Operation.—A 6 in. long thoracotomy was performed just below the angle of the right scapula, and the fifth intercostal space was incised sufficiently to enable a retractor and a Nelson malleable light to be inserted. The upper lobe of the lung was drawn downwards to expose the superior mediastinum, and the vagus nerve picked up with a hook as it passed down a few inches below the thoracic inlet, and cut with long scissors. The incision was closed after the lung had been fully inflated; the whole operation lasted less than a quarter of an hour. The patient's pains were completely abolished for the first time in six months.

Discussion

In two of these five cases the branches of the vagus entering the hilum on the affected side (right in case 1, left in case 2), were cut; and this led to immediate and complete relief of joint symptoms and resolution of admitted to hospital suffer emotional upset Much depends on the constitution of the child Some have a more robust make-up than others, and can thereby withstand emotional deprivation with less adverse effect Their reaction depends, too, on the quality of their previous relationship with parents or guardians Moreover, if an earlier separation has been mishandled the child will naturally tend to react more violently to a second separation, because he is pre-judging it in terms of the last time

We need some means of sorting out these various types of case—the long-term from the short term emotional disturbance, the stable from the unstable, those likely, from their past experience, to settle down readily from those in whom we can expect a turbulent reaction Having screened them in this way, we need the administrative means to place each child according to his particular emotional requirements We need, in fact, a reception centre in each area The success of such a centre will depend on the understanding and insight with which the staff handle these children, and the staff must therefore be carefully selected and specially trained

It is not only the difficult child who may be emotionally disturbed Deprived children are too often judged by their nuisance value If they create no disturbance socially in their environment, it may be falsely assumed that they have settled down Yet some children who suffer serious emotional disorder, because of their personality make up, are unable to express their feelings outwardly Instead, they "bottle up" their emotions within themselves, and so tend to withdraw into a state of dreamy detachment and apparent apathy, which may readily be mistaken for evidence that they have equably accepted their substitute home Such children "take it out" of themselves instead of "taking it out" of their environment Because they abstain from provocative behaviour and appear quiescent, it does not follow that they are less disturbed than their more aggressive fellows

REAL PARENTS AND FOSTER PARENTS

We are familiar with the economic and social conditions which contribute to the disruption of the family unit—unemployment, overcrowded houses, ill health, the death of a parent, and so forth It is perhaps not so widely recognised that the stability of family life may be seriously undermined by emotional factors, especially adverse emotional experiences in the early childhood of the parents A father or mother who has been deprived in childhood may lack the security and maturity to foster lasting family ties Unwittingly such parents perpetuate in their own children the faulty attitudes of which they originally were victims as children Emotional deprivation, which we recognise as an effect of family breakdown, may also be one of its causes If we are to prevent the dissolution of family ties, we must give as much attention to this cause as to the more obvious social factors We must try to rehabilitate these problem parents to avoid another generation of problem children

Much has been said and written about the paramount importance of keeping the family together, but in my experience far too many children are removed from their homes because of material conditions If it is true that adverse emotional factors can disrupt the solidarity of the home, it is equally true that positive emotional factors can do much to offset material degradation No matter how deplorable the physical conditions, and how severe the material privations, where there is strong family affection and close emotional bonds we should never break up that family with the sole object of improving its living conditions Children will tolerate incredible conditions of material deprivation so long as their emotional ties remain intact Conversely, they will fret and become emotionally disturbed, no matter how much we improve their physical surroundings, if in the process they are emotionally deprived By all means let us try to upgrade their living conditions, but always on the foundation of preserving the family unit

If a child has to be taken into care our aim should be to maintain constancy throughout the period, and to avoid disturbing changes in his surroundings and in his new relationships To this end, it is important to make one officer responsible for the child Whatever decisions are taken for the child's welfare, this officer should carry out these procedures direct with the child, and interpret to him the decisions taken on behalf of the department

Similarly we should, as far as possible, avoid moving children from one home to another Once they are placed in an environment, chosen to meet their particular needs, every effort should be made to keep them there, so that they learn to achieve the sense of belonging which is so vital to their well-being

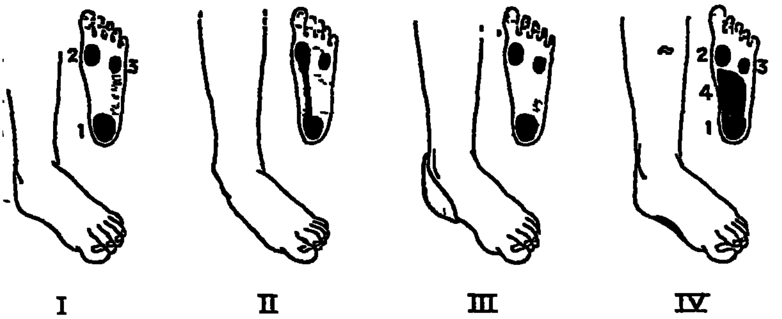
To avoid distressing change we must prepare the ground carefully with prospective foster parents, before asking them to accept the care of a potentially difficult child It is not enough to be satisfied that the foster mother is a stable and kindly soul, that she has warm maternal instincts and personal integrity, and that she maintains a good standard of hygiene and cleanliness in her home These qualities are necessary, but it is equally important to make sure that she has the capacity to understand the child's emotional difficulties and to tolerate his provocative behaviour, should it develop It is vital to find the right foster parents for a particular child Having found them, it is as important to stand by them with encouragement and support, in order to help them to surmount the initial period of adjustment, because at this stage the child may begin to test them It is unfair to them and the child to leave them to cope unaided without regular guidance and technical advice

In my hospital department I bring together a group of these foster-mothers, who are each having to contend with similar problems We meet regularly, and we thrash out together the difficulties which have arisen in the day-to day conduct of the children in their charge There is no doubt that it helps them enormously to discuss their individual problems in a group They take fresh heart at finding that other people have to face similar problems, equally provoking, and by discussion, with my prompting, they come to a deeper understanding of these deprived children, and they learn how to modify their own attitudes.

CONCLUSION

When deprived children present problems in their behaviour, or in their failure to conform within a given environment, we must interpret their conduct in terms of their past experience and emotional make up We must remember the emotional stresses to which they may have been subject, and we must not judge them by our standards, because we are looking in on them from the outside, as secure and well adjusted observers, while they are looking out at us from the inside, from a private world very different to ours—a world fraught with insecurity and doubt

When they resort to provocative behaviour in their efforts to test their new relations, we must remember that they are prompted, not by reason or by cold logical thinking, but by deep seated emotions of which they may be only dimly aware, and certainly not able to control without our help If we fail to provide for them the emotional haven which they need, the consequences may well be far reaching for society and for the child If we succeed, our reward is the child's return to the ranks of well adjusted society



g 2—Manner of weight bearing I, in normal foot (weight is borne on heads of first and fifth metatarsals and on heel), II in flat foot (unnatural weight bearing along inner border of foot), III with corrective heel-seat (normal tripod weight bearing is resumed), IV, with arch-support (a fourth and abnormal weight bearing surface is added)

uffer the disadvantages of the tilted elongated heel It s the first method which in a positive manner, forms and evelops a normally arched foot

The idea of the corrective heel seat is based on two remises

(1) With the forefoot held flat on the floor, inversion of the eel produces an arch, and the greater the inversion the igher is the arch In other words, with the heads of the first nd fifth metatarsals bearing weight normally in the shoe, orrection of the eversion of the heel corrects the flat foot A vertical heel gives the flat foot a normal arch

(2) The growing foot develops and functions in the shape n which it is held—i e, if the growing foot is held and allowed to function in the normal shape it will "set" in the normal shape An extreme example of this was provided by the now discarded Chinese practice of constantly binding the feet of baby girls into a "club" shape With growth they developed fixed club feet Similarly, if we allow children's feet to function with a normal arch, they develop normally shaped feet Moreover, if the foot is so held without arch supports—as the heel seat acts—it will develop a strong arch and strong foot

The heel seat shown in figs 4 and 5 is so constructed that it fits snugly into the back of the shoe, boot, sandal with heels, or even slipper, so long as the stiffening of the heel of the shoe, boot, slipper, or sandal is strong enough to maintain it in position When snug in the back of a shoe the inner surface of the heel-seat is in the shape of a normal heel in the normal vertical position As soon as the child puts on the shoe with a heel-seat, any eversion of the heel is corrected, and it is a virtue of the appliance that the child does not feel any discomfort

Results

Fig 5 shows the immediate effect of the heel seat on the shape of the foot Fig 2 shows the manner of weight bearing

I, in the normal foot

II, in the flat foot with unnatural weight bearing along the inner border of the foot

III, with a corrective heel seat (there is restoration of normal tripod weight bearing)

IV, with an arch support (there is still an abnormal weight-bearing surface)

After heel seats have been inserted, the child's gait is almost immediately and immeasurably improved "Pigeon toed" or splay-feet gaits are corrected, and the child is more agile and less awkward The effect on gait can be assessed from the way in which the shoes wear down Whereas previously the heels of the shoes wore down quickly on the outer side and the heel-seat became deformed, with the corrective heel-seat the heel wears evenly and the shoe maintains its shape Moreover shoes last at least twice as long before they need repair

I have been using heel seats for more than seven years, during which I have prescribed them for about 500 children I find that the average time a child must wear the heel seats constantly before the arch is "set" is from two to two and a half years The arch is then strong and permanent, and no further treatment is required

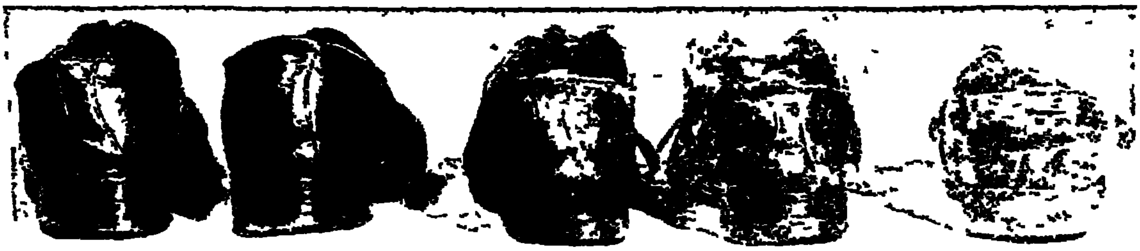


Fig 3—Stages in deformity of shoes of one schoolboy He not only wears down heels on outer side but also deforms heel-seats. When heels of shoes are purposely tilted deformity of heel-seats still results

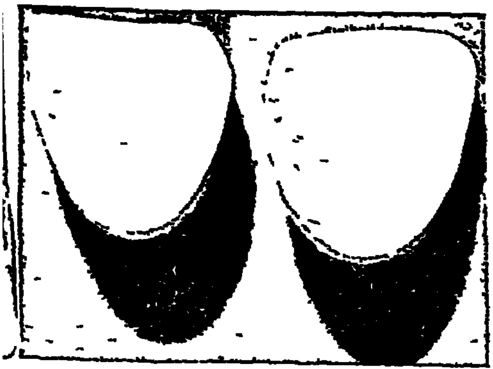

Fig 4—Corrective heel-seats

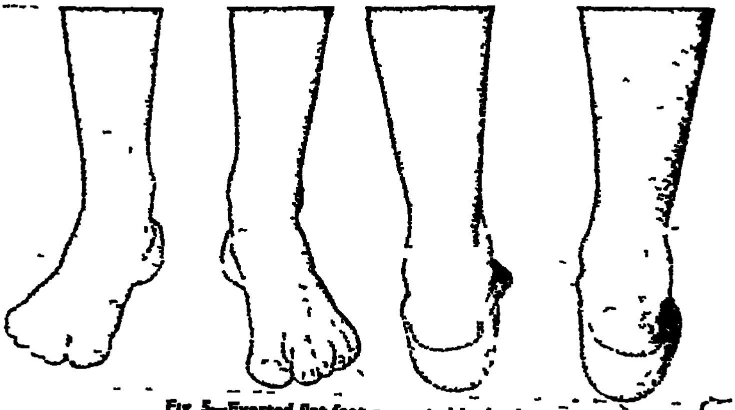

Fig 5—Everted flat feet corrected by heel-seats

In the Mental Hospital *

FACTORY IN A HOSPITAL

A A BAKER
M D Lond, D P M

DEPUTY PHYSICIAN-SUPERINTENDENT, BANSTEAD HOSPITAL, SUTTON

A POLICY of providing work, under factory conditions, for patients in mental hospitals would have far-reaching consequences In this article I shall offer some personal reflections based on experience at Banstead Hospital, where an experimental workshop established by a Medical Research Council unit now employs 40 women and 20 men

WORKING CONDITIONS

We needed to find floor space where a considerable number of patients could work under supervision, and we sought the advice of the local Factory Inspector, who visited the hospital to see the rooms available The most suitable site was a large ward, 80 × 30 ft, which had provided sleeping accommodation for 60 patients Following an active treatment, rehabilitation, and discharge policy, there were sufficient vacancies on other long stay wards to enable this dormitory to be cleared It had adequate lighting, and tables were provided from the hospital workshop by converting old bench-type tables which had been turned out of the wards when modern furniture was introduced

The men do piece work for a motor factory, and the women assemble cardboard boxes, and over a 25-hour working week they have been able to earn between 10s and £2 weekly This may seem a low scale of pay, but it is more than patients can earn by ordinary hospital work such as floor-scrubbing, laundry work, needle work, or ward chores, where pay ranges from 1s to 5s a week. This has led to immediate repercussions in that many of the better workers in the hospital departments have become discontented and wish to move to what is called "the box factory" We have therefore decided that the conditions on which a patient goes to the box factory shall be (1) that he has been an inpatient for several years, (2) that there is a reasonable possibility of his being discharged from hospital, and (3) he should have proved his stability and willingness to work by a period of useful service to the hospital departments It has been realised that patients doing hospital work have been paid too little and the upper level of pay for hospital work has been raised to 10s We hope that the deteriorated psychotic patients on the long-stay wards, who in the past may have spent years sitting in corners, can now be persuaded to do elementary chores in the ward under supervision When they have succeeded at this employment they may be tried outside the ward, with less supervision If this proves successful they can then move to one of the hospital utility departments, such as the laundry or linen room, and after a successful period of work there, can go to the box factory, from which the next step is to leave hospital for ordinary employment

The nurses have shown some ambivalence towards the project Many have been sceptical and felt that factory conditions could not be reproduced within hospital or would fail for lack of cooperation in the patients We are pleased to record that almost all patients have proved far more successful than expected Some ward sisters, understandably, were anxious lest their best ward workers would be taken away and given factory work Again this fear has been largely unjustified, for we have always found it possible to replace the ward workers who have gone to the factory by other patients within the ward There is no doubt that if a patient gets the reputation of being a good ward worker this may prove a disadvantage both to him (or more probably her) and to others on the ward She may unconsciously settle down to a routine where she receives a fair amount of reward and approval for her efforts and therefore be less likely to make the effort to get out of hospital The other patients have less incentive to work, since the work is done for them Thus removal of the good ward worker may lead to fresh progress among others who were previously considered unemployable

EARLY RESULTS

One problem which will soon have to be faced is that many patients working in the factory find that their way of life is highly satisfactory They receive all the benefits of hospital life—full privileges, board and lodging, clothing, television shows, social outings, and even summer holidays They are now able to work under pleasant conditions and receive considerable pocket money Many could well say to us that they cannot obtain such situations for themselves outside hospital and be reluctant to leave However, this has not happened so far Of the first 20 patients who went to our factory some four months ago, 3 have already left hospital The length of stay in hospital of these 3 patients was nineteen, twenty-four, and four years All have gone to full time employment under normal working condition

The improvement in the patients who have been working in the factory is obvious Apart from the 3 who have already left hospital to return to the community, several who were previously on disturbed wards have moved to better wards and others have earned more privileges Ward sisters spontaneously say that these patients take more pride in their appearance, have more self-confidence, and are showing a fresh interest not only in their life in the hospital but in the possibilities of leaving This is true of patients who were considered "institutionalised" and for whom the prognosis under ordinary hospital conditions had been very poor

NEW USES FOR OUR MENTAL HOSPITALS

There are eight other large mental hospitals within a few miles of Banstead Hospital, and I estimate that together the mental hospitals of the area contain several thousand potentially employable people In the present state of employment, when there are more jobs than people and when firms are willing to offer piece work, it is relatively easy to arrange work-therapy for the hospital patient If the hospital system were reorganised so that work-therapy replaced the traditional occupational therapy, there might be disastrous results should under employment cease, and we must not forget that the factory work introduced into some mental hospitals in the early 1930s was abandoned during the economic depression On the other hand, it is clear that the desire to create normal living and working conditions for mental patients is part of the general trend towards their more humane treatment, and on this if no other ground our work therapy policy should be continued

If many patients prove their ability to work at a level which will enable them to be self-supporting outside hospital, we shall have to face another social problem Only a third of these long stay patients have any known relative, friend, or contact outside hospital, and this means that when they are well enough to leave hospital it will be necessary to find for many of them accommodation as well as work Even with the improvement in housing in the past year or two it is still difficult for a healthy and active person to find satisfactory lodging, and for our long stay patients, whose initiative and drive is diminished, it will be an even harder task We feel,

* A group of articles chiefly concerned with the value of active occupation and work for mental patients and the means whereby it is best provided

f E E G abnormalities in children with pains[1] Such a reponderance, small though it is, is however made up argely of focal spikes, which we do not consider to be ndicative of epilepsy

If "epileptiform" records alone are compared in the wo groups (table II), the children without pains show ather more abnormalities in the resting records, while f children with a normal resting record those with bdominal pains produce more "epileptic" responses ith hyperpnœa and photic stimulation

None of the differences between our two groups is tatistically significant at the 5% level of probability

Discussion

It is difficult to discuss "abdominal epilepsy" without lefining "epilepsy," the undefinable Our remarks are onfined to an alleged association between recurrent bdominal pain and epilepsy Our conclusions are based on the premise that a group of children with epilepsy shows a significantly higher proportion of characteristically abnormal E E G s than does a group of non-epileptics

In all four groups of children—hospital and school children, with or without recurrent abdominal pains—the distribution of abnormal E E G s was similar The comparative figures are substantially unaffected, whether resting and/or evoked records are considered The similarity between the four groups suggests that E E G abnormalities and recurrent abdominal pains are not associated or inherently related

We infer that the suggested causal relationship between abdominal pains and cerebral dysrhythmia may be based on (*a*) a failure to compare E E G s with those of apparently normal children of similar ages and attainments, and (*b*) a consequent acceptance of E E G variants as indicative of epilepsy

We realise that a small proportion of children with epilepsy also have recurrent abdominal pains Most, if not all, however, can be recognised if the history of fits, turns faints, spells, &c, is meticulously taken, as we attempted to do in our children with pains and in our control series As a sole manifestation of epilepsy, abdominal pain must be rare But even the overt association of the two is relatively unusual, from our figures, and if the few children suffering from fits had not been excluded from our series the results would have been affected only to an insignificant degree Our cases differ in many respects from the series of 33 children with "cyclical vomiting" and a remarkably high number of E E G abnormalities reported by Millichap et al (1955) In that series there was admittedly some selection of cases (14 children had a history of fits), vomiting was periodic in type and prolonged, and abdominal pains occurred in only about half the patients

Since an abnormal E E G is admittedly much commoner in epileptic than in non-epileptic patients, our findings suggest the corollary is also true and that *children with no symptoms other than recurrent abdominal pains* should no more be considered "epileptic" than children without them

Summary

Electro-encephalograms were taken from 133 children with recurrent abdominal pains but no demonstrable organic disease and from 133 children of corresponding ages without abdominal pains A very small number with a history of fits were excluded from both groups

In the two groups the proportion with epileptiform E E G s was almost identical

Since epileptiform E E G s are significantly commoner in epileptic than in non-epileptic patients these findings lend no support to the view that there is a relationship between epilepsy and recurrent abdominal pains in childhood

We are indebted to Dr Grey Walter and to Miss E H L Duncan, M A., B.SC., for helpful advice, and also to the three recordists, Mrs A B Spear, Miss J P Rockett, and Miss V D Heaven, whose patient work with the children was of special importance

RETROCLAVICULAR BLOCK DISSECTION IN THE DIAGNOSIS OF SARCOIDOSIS OF THE LUNG

Bo Carstensen
M D
PHYSICIAN IN CHIEF,
SOLLIDEN, SWEDEN

Axel Odelberg
M D
SURGEON IN-CHIEF,
OSTERSUND, SWEDEN

Fredrik Wahlgren
M D
HEAD OF DEPARTMENT OF PATHOLOGY, SÖDERSJUKHUSET,
STOCKHOLM, SWEDEN

Sarcoidosis of the lung is less uncommon, and less benign, than was formerly supposed Increased knowledge of the disease, and more widespread use of tuberculin tests and mass radiography have been largely responsible for this disease being diagnosed more frequently.

At Solliden Sanatorium, which serves a population of 145 000 about 300 cases of sarcoidosis of the lung have been detected in the past five years

Criteria for Diagnosis

Unequivocal diagnosis of sarcoidosis of the lung is impossible We have adopted the following criteria

(1) The patient should have the typical history and signs and/or radiographic evidence The relative paucity of symptoms contrasts sharply with the extent of the lesions, which are widespread Hyperglobulinæmia should be sought

(2) Other diseases (e g, tuberculosis, pneumoconiosis, Hodgkin's disease, neoplasm, and the mycoses) should be excluded

(3) Corroborative histological evidence should be obtained by biopsy of lymph-nodes and by Kveim's test

Sarcoidosis can be diagnosed when only criteria (1) and (2) are satisfied, provided that lesions are found in at least three organs, but we are never fully satisfied without positive evidence from biopsy Most cases of suspected sarcoidosis of the lung are discovered by radiography, and in such cases there are commonly no enlarged superficial lymph-nodes or cutaneous lesions In such cases we have found retrocl

---

[1] Walter (1950) has shown that so called diagnostic epileptic patterns can be evoked from normal resting records in some "normal" persons, a finding confirmed by Jewesbury (1952) Gastaut (1953) suggests that these evoked responses are probably better regarded as a measure of the convulsive threshold rather than as diagnostic of epilepsy

Disease He believes in local government and in a real, everyday, practical, partnership of local authorities with family doctors in the care of the sick which is why Bristol can show so interesting a group of clinics and potential health centres—the latest (the fifth to be built since the war) opened only the other day He has stood always for the integration of medical work and has often been able to make it a reality Long ago, as professor of preventive medicine and M O H, he was offering chemical and bacteriological services to practitioners, he coordinated the school services with those for maternity and child welfare, and under his inspiration the city was developing its hospitals with consultants and specialists drawn from the voluntary hospitals Latterly he has tended to think of the future M O H as increasingly an epidemiologist in the wide sense, and characteristically has acted on this thought by arranging for a medical statistical section to be set up as a joint venture of the city and university During the war [illegible] again in 1951 he visited America, and in 1949—the [illegible]r of his presidency of the Society of Medical Officers [illegible] Health—he spent four months in Greece as expert [illegible]viser to the American Mission *Looking at Pairy*, [illegible]e sees that public health is the career for excitement

Influenza

Laboratory confirmation has been received of virus-A influenza in the Stowmarket area There is similar confirmation in cases in the Camberley area, in a school outbreak at Otley, Yorkshire, and in an army unit at Caterham Influenza-like outbreaks continue to be reported from other areas Among these are outbreaks in two public schools—one in Berkshire and one in Lancashire There are indications of an increasing spread of virus-A influenza in many parts of the country but, on the whole, cases have been clinically mild, and the weekly claims for sickness benefit have not been much affected

Third Quarter in England and Wales

The Registrar-General has already published some preliminary figures for the September quarter of 1955[1] A more detailed analysis[2] has now appeared There were 3493 notifications of poliomyelitis in the quarter and the death-rate was 9 per million population In the corresponding quarter of 1954 there were 880 notifications, with a death-rate of 4 per million population Tuberculosis notifications in England and Wales totalled 9239 compared with 10,204 in the same period of 1954 The tuberculosis death-rate was 116 per million population, as against 146 per million the year before

Parliament

Hospital Farms

Replying to a short debate in the House of Commons on Jan 30, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the basis on which farming at mental hospitals had been conducted had always been accepted as the need for a green belt to provide security and privacy, and outdoor occupation for suitable patients There was no question of cutting down that type of farming The third basis was the value of the farm and garden produce in the diet of patients, particularly where large supplies of milk and vegetables were not always available As long ago as 1948 it was apparent that farming in many hospitals had developed into a large-scale venture undertaken for its own sake A circular was then sent to hospital authorities pointing out that the criteria for farming should fall into the three categories which she had mentioned Not much action was taken after this warning People who had prize farms tended to hang on to them A departmental committee was set up in 1952 to investigate the farming activities of these hospitals It reached the conclusion that Government's criteria were not always being observed It found that few patients were being employed on farm work as a form of occupational therapy Only 3 3% of male patients were employed on farming and 3 2% in gardening, and only 0 3% of female patients were employed The complexity of modern farming tended to make it less easy to use patients and there had been a steady increase of outside staff on these farms The legal position was that hospital management committees had no authority to run a farm except in so far as it provided occupation or food for patients The present position was that at Oct 31 last decisions had been reached about 126 farms Of these 47 were to cease, and 38 had to reduce their activities A further 81 farms had been surveyed, about which decisions had not been made

QUESTION TIME

Social Services and the Family

Replying to questions, Major GWILYM LLOYD GEORGE, the Home Secretary, said he had considered with care and sympathy the proposals made by Mrs Fisher's deputation in July last year, for a general inquiry into the social services concerned with the family, and by a deputation from the Magistrates' Association in November that the suggested inquiry should be coupled with a review of the working of the juvenile court system in England and Wales Mrs Fisher's deputation had drawn attention to the need for better coordination of the services in question This matter had already received much attention in the departments concerned, and the Government proposed to follow up, by departmental study and administrative action, the steps already taken to improve coördination of the local services at all levels and to secure a combined approach to a family's problems As regards the proposals of the Magistrates' Association for a review of the work of the juvenile courts and the treatment of children coming before them, he had come to the conclusion that the time was ripe for a new study of this subject, and he proposed to set up a committee to consider and make recommendations on the working of the relevant provisions of the Children and Young Persons Act, 1933, as amended

Both deputations had also drawn attention to the need to pay more attention to preventive work, and the committee's terms of reference would include consideration of the powers and duties of local authorities under the Children Act for preventing the suffering of children neglected in their own homes The membership and exact terms of reference of the committee would be announced in due course In order that interested organisations might have time to consider what evidence to submit, he contemplated that the committee should not start work before the autumn The Government believed that the action which he had announced would meet the situation and be of more practical value than a wide ranging general inquiry at the present time

Remand Centres

Replying to a question, Major LLOYD GEORGE said that he regretted that the need to restrict expenditure on Government parately from the main excised portion. Two large rainage tubes were inserted down to the bed of the xcised portion of the pancreas, discharged freely for a onth and were removed six weeks later. Biopsy owed an insulin tumour strangled by fibrous tissue.

The patient weighed 10 st. $11\frac{3}{4}$ lb. on Sept. 20, 1952 nd 9 st. $10\frac{1}{2}$ lb. on June 20, 1955.

Numerous tests applied to this patient excluded other ossible causes of her condition. Serial sections of the xcised portion of the pancreas have not yet been xamined; but, in view of the pathological report on he nodule, it is perhaps just as well that the more xtensive operation was done.

Reviews of Books

Clinical Neurology

A. B. BAKER, M.D., professor of neurology, University of Minnesota. New York: Hoeber. London: Cassell. 1955. Vols. I, II, and III. Pp. 2021. 20 guineas the set.

IN a book remarkable for the quality of the printing and illustration the thoughts of 64 American neurologists have been gathered. The mention of a few names will indicate the happiness of the editor's choices: Jasper (electro-encephalography), Woltmann and Kernohan (peripheral nerves), Breutsch (symptomatology and pathology of neurosyphilis), Kunkle and Wolff (headache), and Courville (cerebral anoxia). The book is a success and deserves a place in the reference library or on the bookshelf of the expert.

There are, however, some notable omissions: the effect of occlusion of the basilar and vertebral arteries is not considered in the chapter on vascular disease; there is no mention of peripheral neuropathies or cerebellar degeneration in association with neoplasia; some of the more recent evidence on the metabolic disorder in Wilson's disease has not been included; and the neurological effects of cervical spondylosis receive no notice.

Dr. Baker's aim was to present in encyclopædic form current knowledge of neurological diseases both common and rare, and to give an account of the many extensions of neurology into other branches of medicine. The first part of the first volume illustrates his attempt to systematise this amorphous subject. Thus, there are sections on history-taking and the technique of examination (admirably presented), followed by a fairly lengthy exposition of the accessory diagnostic methods. Later chapters deal with basic subjects, such as cerebral localisation, agnosia and aphasia, and cerebral anoxia. It is these basic chapters that first deviate from the editorial aim; for, although the radiology and the electro-encephalography are presented very lucidly, the consideration of the diagnostic implications of ophthalmology tails off into some untidy guerrilla warfare relating to angiomatosis retinæ, Wilson's disease, dystrophia myotonica, and other matters.

After the basic principles, there are essays, rather than chapters, on the various aspects of neurology. The very brevity of some of the contributions carries dogmatism at times too far. Moreover, some writers, in their attempts to give an authoritative verdict, have introduced contradictions; thus, the concept of narcolepsy on p. 1920 is totally at variance with that expressed on p. 1204.

In so large and complex an undertaking, such faults are inevitable, and the good easily outweighs the bad. Dr. Baker and his team have made a definite contribution to medical literature and their work will undoubtedly gain in value as it moves through further editions.

Whys and Wherefores in Tuberculosis

GEORGE DAY, M.D. London: National Association for the Prevention of Tuberculosis. 1955. Pp. 44. 3s. 6d.

A DELIGHTFULLY written booklet for patients by a physician of exceptional experience in the psychological aspects of tuberculosis. A short historical review is followed by concise common-sense epidemiological information, easily appreciated by patients. The factors affecting resistance are briefly examined and the different aspects of treatment simply and clearly discussed. While some medical readers may question one or two statements (e.g., "B.C.G. or vole bacillus vaccination will probably become accepted as a routine for new-born babies") every reader will be stimulated by this brief and intelligent review.

Anatomie radiographique du massif facial

M. BOUCHET, otorhinolaryngologiste des Hôpitaux de Paris; G. DULAC, electro radiologiste, ancien chef de service de la Fondation Curie; with the collaboration of R. PAILLEP. Paris: Masson. 1955. Pp. 187. Fr. 2800.

THE interpretation of radiographs of the classical projections of the nose, nasal sinus, and adjacent structures of the face depends on a sound knowledge of the detailed radiological anatomy of this region. The authors carefully define each projection and then describe its features with the aid of simple diagrams in the first instance, followed by more complicated "schemas" as extra details are added.

Nine of the commonly used projections are thus dealt with, and then follows a brief section on tomography in the anteroposterior plane, treated in the same way. The second part of the book is devoted to illustrations of radiographs, with fully annotated diagrams. The radiographs are designed as an exercise in interpretation of the standard projections and of some of their variants.

The authors hope to improve the standard of interpretation of "sinus" films, since they regard the reports "sinuses clear" and "sinuses opaque" as often very inadequate. To anyone who takes the trouble to work conscientiously through the "schemas," interpretation should be relatively easy, for the basic anatomy should then present no difficulty. The book is well produced and easy to understand by anyone with an elementary knowledge of French.

Psychosomatics

MAX HAMILTON, M.D., senior lecturer, department of psychiatry, University of Leeds School of Medicine. London: Chapman & Hall. 1955. Pp. 225. 21s.

DR. HAMILTON has covered the subject in an admirable way, avoiding diffuse theoretical discussion for mainly factual and experimental findings. His book is a readable and successful attempt to present, from a scientific point of view, emotional and environmental factors in disease.

The first chapter discusses the physiology of the emotions, with many references to fundamental work, such as that of Cannon; and later chapters describe such conditions as asthma, peptic ulcer, hypertension, urticaria, and many others.

Throughout, there is an unusually balanced presentation of the subject. The main points of evidence are given, and certain extremist points of view are criticised.

Smoking and its Effects

With Special Reference to Lung Cancer. SIDNEY RUSS, C.B.E., D.SC., emeritus professor, University of London. London: Hutchinson's Scientific and Technical Publications. 1955. Pp. 141. 8s. 6d.

PROFESSOR RUSS is here writing for the general reader, and sets out to cover the history and practice of smoking, including opium and hemp as well as tobacco.

Nine-tenths of his book, however, is concerned with tobacco-smoking, and nearly half of it with the special problem of smoking and lung cancer. To succeed in summarising the history, methods, and implications of smoking in so small a space would indeed be a feat; and though the style is easy and readable the arrangement of material is uneven and sometimes haphazard. The early chapters contain interesting information, but their general effect is sketchy, and the arguments put forward are open to question. The author says: "Smoking is a very deep rooted habit in the peoples of the world. Let us not try to stop it by methods which are almost bound to fail, but supplant the poppy and hemp by the tobacco plant." Though many would agree with him, even this small book contains evidence to suggest that the answer is not quite as simple as that.

Having spent most of his life directing and working in a laboratory for cancer research, Professor Russ gets into his stride when he comes to his main theme—the relation between tobacco-smoking and bronchial carcinoma. This

His Lordship thought that some such provision should be made, as the £750 belonging to the son would not last for ever. Maintenance ought not to be limited to the mere provision of food, clothing, and shelter, but should be extended to what were known as "comforts" in institutions of the kind in which the plaintiff now was. His Lordship did not think that the beneficiaries would consider it unfair on them if he altered the provisions of the will of the mother so that the son would be provided with 10s. a week, and he would order that the son should receive that sum out of the estate of the mother as from her death for his life or until cesser of his disability or until further order.

In re Pringle, Deceased.—*Chancery Division.* Vaisey, *J.* Feb. 1, 1956. B. S. Tatham (Crossman, Block & Co. for McKenzie Bell & Sons, Sunderland); K. W. Rubin (Bentleys, Stokes & Lowless r Criddle, Ord & Mickle, Newcastle upon Tyne) and Raymond alton (Speechly, Mumford & Craig for Saul & Lightfoot, Carlisle).

The Doctor's Bag

The director of a company of photographic printers d free-lance photographers was carrying photographic uipment in a shooting-brake for the purpose of his isiness. The car was licensed as a private car and he as charged with the offence of unlawfully using the car ithout the proper rate of duty—namely, the higher rate pplicable to goods vehicles—having been paid. The ustices dismissed the charge on the ground that the hooting-brake was not constructed or adapted for the arriage of goods, because they considered that "if the est is the nature of the 'goods' irrespective of the type f vehicle, then the carriage of a doctor's professional nstruments or a lawyer's text-books in a private car ight result in these offences." The prosecutor appealed o the Divisional Court, and counsel on his behalf agreed hat a doctor carrying his bag in a shooting-brake would e liable to the higher rate of duty, but not if he were sing a private saloon car.

Lord GODDARD, C.J., said that a shooting-brake was onstructed or adapted for the carriage of goods and if was used for that purpose the higher rate of duty had o be paid. However, if such a vehicle was not used n the carriage of goods, for hire or reward, or in connection with a trade or business it was not liable to the igher duty. It was not necessary for the court to ecide in the present case whether a doctor using a hooting-brake and carrying his bag of instruments with im would be liable, but his Lordship was far from saying hat it might not be so. The director of the photographic ompany was therefore liable to pay the higher duty. he case would go back to the justices with a direction hat an offence had been committed.

Taylor v. Thompson.—*Queen's Bench Division (Divisional Court).* ord Goddard, *C.J.*, Hilbery and Stable, *JJ.* Jan. 26, 1956. ounsel and solicitors: Rodger Winn (Treasury Solicitor).

C. J. ELLIS
Barrister-at-Law

Legislation on Sexual Crimes

The Government have decided[1] to introduce a Bill to onsolidate the statute law relating to sexual crimes, nd to the abduction, procuration, and prostitution of omen, and some kindred offences.

The proposed corrections and minor improvements include larification of drafting and removal of anomalies. Thus, he maximum punishment for attempted incest in the case f a man is two years, but in the case of a woman seven years. he reason is that the punishment for a man was originally wo years' hard labour—regarded as heavier punishment than even years' imprisonment—but in 1948 hard labour was abolished without any adjustment of sentences. The Government now propose to reduce the maximum penalty for this offence by a woman to two years.

The Government's decision to consolidate the existing law is not necessarily an indication that they have decided against major reforms. The proposed Bill will be introduced under the Consolidation of Enactments (Procedure) Act, 1949, which is designed to facilitate the consolidation from time to time of various portions of the statute law.

[1] Consolidation of Enactments relating to Sexual Offences, etc. Memorandum. H.M. Stationery Office. 9d.

In England Now

A Running Commentary by Peripatetic Correspondents

HE got off his motor-bike and crossed the road towards me, but it was only as he reached the car that I recognised Kenneth. We felt awkward and shy with each other, and though I walked to the sidecar to meet his wife and baby daughter, my manner seemed false even to me. Normally, I am at ease with patients, but now I found myself over-hearty, embarrassed at the sudden reminder of a former intimacy.

Kenneth and I were intimate enough in the early months of 1947. I inherited him when—on my return from the war—a senior colleague handed me a block of his tuberculosis beds. Kenneth had collected several medals with the Commandos—also pulmonary tuberculosis, and, when I first saw him, after a right pneumonectomy in those pre-streptomycin days, he lay in bed emaciated and hectic. His bronchopleural fistula on the right side had led to mixed tuberculous and pyogenic empyema, and in his remaining lung a fresh focus was accompanied by a pleural effusion. By way of introduction, my colleague whispered his history to me at the foot of the bed, murmured of the hopelessness of any treatment, and moved on. Keen ears picked up the words and I saw Kenneth turn his face to the wall.

I came and sat by his bed late that night, and at first he tried hard to be indifferent. Without preliminaries, I sketched out a position that he might have found himself in as a Commando—retreat cut off, wounded, surrounded by a powerful, well-armed and invisible enemy. What, I asked, would he have done—surrendered? His reply confirmed my estimate of his quality. I reminded him of what he had overheard that morning, stressing that it was a sound opinion that none would dispute—was he still prepared to throw defiance at the enemy and fight back? Again, he left me in no doubt. I outlined his programme for the next two years—pointing out the pain, hardship, and boredom he must cheerfully accept—but as we shook hands I knew he would win.

When he left for industrial training in 1949, he was a little twisted in body—a 10-rib Schede does that—but his spirit was straight enough.

Driving away after that short, embarrassed meeting at my car-door, I could not help thinking how easy streptomycin and isoniazid had now made it all, but no-one could claim they had made it more interesting.

* * *

The county town lies some fifteen miles to the east of our village, and we can reach it by either of two roads—the old road or the new road. These run parallel and are nowhere more than a mile apart, but they are totally different in character. The new road has attracted to itself all the horrors of modern life, while the old road remains exactly as it has been for hundreds of years.

The new road passes through three villages, each with a charming name, and not so many years ago each was as beautiful as its name. Now the dominating feature in all three is the garage, guarded by rows of tall petrol pumps, littered about with cars in various stages of repair and innumerable advertisements. Half way along the road is a vast caravan site, where twenty years ago was a shady wood. Two miles further along is a sort of knacker's yard of old cars in every stage of disembowelment.

Then saddest of all we come to *Ye Olde Traveller's Rest*, a monument of imitation antique, its beams and panelling of plywood, its windows leaded with strips of black paper. Along the new road the trees and coppices are being gradually cut down, and little bungalows built in their stead.

How different is the old road. We feel we owe it an apology for being in a car; we ought to be in a wagonette, a stanhope, or at least a dog-cart. It passes through two villages; in the first is an ancient smithy, where once many horses put on their shoes and where the one remaining horse is still shod. As the blacksmith says, four hooves give him a little shoeing practice. In the second village is a wheelwright, who does better than the blacksmith, for there are more tractor-drawn farm carts needing wheels than farm horses needing shoes. Leaving

THE LANCET
LONDON   SATURDAY, FEB 11, 1956

Treatment of Infective Hepatitis

As we have no specific drug with which to attack agent causing infective hepatitis, treatment must irected to providing the best conditions for natural very In general this means regulation of diet and ision of rest The practical questions which arise what kind of food should be given and for how long patient should be confined to bed Different views e been expressed on these points,[1–5] but the wers can best be sought by carrying out a large and refully controlled therapeutic trial, as has recently been done by an American team working in the Far East [6] In a series of studies, patients suffering from infective hepatitis were allotted at random to different treatment groups The design of the experiment was arranged so that the doctor deciding to admit a patient to the investigation did not know what treatment the patient was to receive Careful checks were made to ensure that the treatment ordered was actually carried out The first inquiry into the effect of diet showed that patients forced to eat an abundance of calories, protein, and vitamins throughout their stay in hospital improved more rapidly than those patients eating only what they chose from a normally nutritious diet, but when they were examined a year later no difference was discernible between the two groups In a second investigation, diets containing either 3000 or 4000 calories (of which 19% were supplied as protein) were compared with ones of the same calorie values but containing only 11% as protein The diets with the higher protein content were associated with shorter illnesses At a follow-up examination the patients who had received the high-protein high-calorie diet showed a slightly higher incidence of mild residual abnormalities compared with the other three groups

A study of the effect of rest was more surprising acutely ill patients improved just as rapidly when they were allowed up and about the ward at will as when they were strictly confined to bed The duration of the acute illness, defined as the time from admission the finding of a serum-bilirubin level of 1 5 mg per 0 ml or less and a bromsulphalein retention of 5% or less in forty-five minutes, was similar with the two regimens There was no evidence that enforced bed rest led to a more rapid disappearance of hepatic tenderness or enlargement The recurrence of symptoms after discharge to duty was equal in the two groups, and at examination after a year no significant difference was noted In a further study, patients were subjected to severe exercise at a physical reconditioning centre, while others were kept in hospital and allowed to rest at will The strenuous activity began as soon as the acute stage of the illness (as previously defined) had subsided Those in the early-exercise group later showed significantly more minor abnormalities, such as rises in serum-bilirubin and bromsulphalein retention, as well as more recurrences of symptoms and hepatomegaly, but these features disappeared in spite of continued exercise When seen later, this group had more complaints of right-upper-quadrant pain and significantly more tender livers Chalmers et al believe, however, that these findings were associated with little clinical disability and that no definitely harmful effects were caused by this strenuous exertion during convalescence

It is important to emphasise that these experiments were carried out on previously well-fed healthy males *during military service It would be unjustifiable to* transfer the conclusions to the treatment of all cases of infective hepatitis Furthermore, as all the patients were transferred to a special centre, the various treatments were begun on the average about ten days after the onset of symptoms The results therefore do not apply to the initial stage of the disease, when strict rest may be of greater importance The results of a *high-protein diet have often in the past been conflicting,*[7–10] and from the clinical viewpoint the reduction in the duration of the illness, which is apparently sometimes achieved by diet, is generally not great In this recent trial the significance of some of the mild residual clinical features which appeared in those exercised early or forced to eat large high-protein diets is difficult to determine Hence, a doctor should hesitate before adding to a patient's discomfort by forcing on him a diet much greater than he feels inclined to eat Nevertheless, in treating patients of military age, Chalmers et al make certain recommendations as a result of these studies The daily diet for a patient with infective hepatitis should contain about 3000 calories, with approximately 150 g each of protein and fat During the stage of severe anorexia *the patient should be encouraged to take frequent* small feeds Although the high-protein diet was shown on the average to hasten recovery, critically ill patients with severe liver damage may be harmed by excess protein and they clearly require special treatment with only a maintenance amount of protein Chalmers et al believe that patients should stay in bed as long as acute symptoms persist, but as soon as they begin to feel well they should be allowed to get up regardless of the degree of jaundice Rest in bed for one hour after each meal should be enforced, but otherwise they should be permitted the freedom of the ward This moderate activity avoids the usual delay in overcoming the effects of long rest in bed and appreciably shortens the stay in hospital

satisfactory, and if there is lack of response this should be *a signal, not automatically* to start ringing the changes of other newer and more powerful antibiotics, but to reassess the case and reconsider the diagnosis The real indications for the tetracyclines need to be more clearly defined, there must be very few absolute primary indications for their use

These and other points related to the use of antibiotics need further study, for surely there are few other fields of medicine at present where *muddled thinking so abounds*

There was much to be said for the arrangements, before the tetracyclines were generally released in April of last year, by which these drugs were available through hospitals for prescribed conditions While I do not advocate a reversal *to this system in its entirety,* it did at least make one think twice before using the drugs It was a pity that similar restrictions did not apply to the young hospital residents, who were perhaps much more liberal with the tetracyclines than the general practitioners

he New Zealand government's bold step should lead our n Ministry of Health and all the leaders of our profession hink again how best to apply a rational policy on the use he antibiotics

Beckenham, Kent JOHN FRY

THE STRATEGY OF MEDICAL RESEARCH

SIR,—It is a pleasure to read your praise (Jan 7) of the ntly published volumes dealing with research in the ited States You rightly praise the unexpected finding ich leads to great results and deprecate the "local service tion" approach

You criticise the fact that a crutch will fetch more money han a hearing aid Any disease can have a crutch as a motto or sign You should praise the public relations of the friends of poliomyelitis and deprecate the tardiness of the friends of the *deaf There is much good will in the public toward* research, and all it needs is intelligent direction No one will have anything but praise for your support of fundamental research But practicality should not damn research either

There is a small factual error The Rockefeller Institute *is totally independent of the Rockefeller Foundation*

The last paragraph of your editorial causes the greatest alarm and I would like to make some comments These views of mine have developed over a period of years You state "this work should make us appreciate the value of our system by which grants to the universities and Medical Research Council are made through the Privy Council and are thus beyond any ill informed or undesirable political pressures" No doubt you mean governmental pressures and not medico political pressures The important point is to know how much money travels via the university or via non M R C channels to the research-worker and how much via the M R C Would it be fair to say that the M R C has a *virtual monopoly* of research monies? The basis of a democracy is a combination of independent and competing units, and research should be on the same sound basis If vitamin Q was being investigated by D A with M R C funds, would D B's request *for funds* to the M R C be well received if his views were divergent from those of the M R C 's advisers?

As the U S A was not considered to have a common law, the Congress formally enacted, in 1890, the "Sherman Anti trust Act" to declare illegal "every contract in restraint *of trade,"*[1] *to help* law abiding citizens who felt victimised Owing to continual vigilance this has been a useful statute The size of the groups involved is not important, and combinations which contribute to efficiency have not been destroyed

Whether the M R C acts in restraint of trade (in this case research) *depends on the activity* and strength of the competing agencies, which in this case would seem to be the local hospital committees and the universities The threatening aspect is the growth of the power of the M R C Concerted action is not monopoly, and the M R C has played a leading part in joint *clinical investigations* which deserves great praise

In discussing the Sherman Antitrust Act, Arnold[1] has said

> "Whether some of the largest and most exacting monopolies are directed by men with *criminal or benevolent* intentions is purely a matter of accident It is the results growing out of their operation which are significant for our purpose Actually the violation of antitrust laws by great industrial leaders does not usually fall in the class of *offences* which involve *moral turpitude* It is more like passing through a traffic light at high speed without the intention of *harming anyone This makes it less immoral* but not less dangerous"

Research *money with strings attached* is not dangerous if one can turn elsewhere, but research money given freely may be restrictive if no other source is available

State University of Iowa,
Iowa City,
Iowa, U S A J MACLEAN SMITH

EPIDEMIC KERATO-CONJUNCTIVITIS

SIR,—I was interested to read your annotation (Jan 28) which mentioned *an* outbreak of pharyngo conjunctival fever in America I have recently seen one or more cases of this condition in my own practice in South East London

On Jan 7 I saw A, aged 7, who had fallen ill the day before She complained of headache, a sore eye, loss of appetite, and general malaise She was pyrexial and had severe conjunctivitis in the right eye The pharynx was slightly injected and there were a few enlarged cervical *glands* The patient was treated with penicillin eye ointment, and later with sulphacetamide drops Neither of these affected the conjunctivitis The pyrexia persisted until the ninth day of the disease, when the temperature dropped to normal and the eye *condition began to clear* The *next day* the child was perfectly well Since the clinical picture conformed to the description of pharyngo conjunctival fever,[1] blood was sent for serological examination On the thirteenth day of the illness complement fixation tests, kindly carried out for me by the *Virus* Reference Laboratory, showed evidence of recent infection with the A P C group of viruses Six or seven days before she fell ill, this child was in contact with another child, who was reported to have had a similar illness This history fitted in with the incubation period of pharyngo conjunctival fever, but I later learned from the *family* doctor concerned that the second child had had a simple upper respiratory infection without conjunctivitis

On Jan 10 two brothers, B and C, aged 6 and 3, living in a self contained flat above A, began to have a similar illness, which lasted only four days B had conjunctivitis *in one eye,* but C had no eye involvement No serological investigations were made in these two cases

On Jan 14 A's mother had an attack of influenza, which lasted three days, and on Jan 13 the mother of B and C developed chickenpox

In view of the mild clinical course of pharyngo conjunctival fever, this *condition may* be *not* uncommon in this country

London, S E 26 R N JACKSON

BLOOD-TRANSFUSION

SIR,—Your leader (Dec 31) *and* subsequent *correspondence* reveal some ignorance of the scope and quantity of emergency work done at smaller provincial hospitals

The suggestion that the pathologist should be got out to perform every emergency cross match has already been dealt with If this proposal were *logically* extended, "the most expert available" surgeon and "the most expert available" anæsthetist should also be called out of bed to every emergency, and I have yet to hear that this is done

The suggestion that hospitals which have no resident clinical pathologist should not undertake *work for* which transfusion is often needed is obviously absurd At this hospital with some 350 beds (and there must be hundreds of a similar size and type), which has large orthopædic and maternity departments, as well as acute medical and surgical beds, emergencies requiring transfusion at *night are frequent* in one department or another Is it seriously suggested that all these emergencies should be sent to the nearest hospital with a resident pathologist, probably 25 miles away? Far from having a resident pathologist, we have but one registrar, in orthopædics, *and no resident* surgical officer, and a high proportion of the resident staff are in the pre registration stage

Lastly, as regards the practice of using *technicians for* emergency grouping and cross matching, I would point out that of the staff of seven in *this laboratory four* are either students or junior technicians, and I assume it is not suggested

[1] Arnold T et al The Sherman Antitrust Act and its Enforcement Law and Contemporary Problems vol 7, Durham North Carolina

[1] Ryan R W O Rourke J I Iser G *Arch Ophthal, Chicago,* 1955, 54 211

VAN HEYNINGEN and WEINER,[11] however, have demonstrated that the composition of arm-bag sweat is always more concentrated than general body sweat, and therefore calculations of balances based on the arm-bag method will exaggerate salt loss. Since much of the published work on sodium-chloride balances depends on arm-bag sweat analyses, it may be that salt requirements in the heat have been overestimated. It is interesting that Nigerians are said to have an intake of only 7 g. of salt a day or even less, and it has also been reported that their sweat is more dilute than that of fully acclimatised Europeans.[12]

So far, most physiological work on the effect of long-continued exposure to heat has been concerned with the initial stages of acclimatisation, and until these were worked out it was not possible to distinguish clearly the more remote effects. The importance of studying these is evident; for, until the demands of the environment are understood, the complications introduced by disease will be much harder to comprehend. Future work should include not only the young men who have hitherto been the main subjects of climatic physiologists, but women and children as well. Normal physiological values should be established for tropical countries, since textbook figures are often applicable only to temperate zones. For example, the average daily urine output is usually given as 1500 ml., but in Singapore ADAM[13] has shown that the daily urinary output averages 1200 ml., and LADELL et al.[14] found that in Shaiba, before the extreme hot weather, the output was about 1000 ml., while in extremely hot conditions it fell to 700 ml. Until considerably more work has been done in the tropics, much of the advice given on salt and water requirements must remain empirical.

The Future of Work

AUTOMATION is a new word. The control of machines by machines is not a new idea, but the war-time development of electronics and of machines which can sum up a situation and adjust a process is making it a frequent idea in practice, and the automatic factory seems to lie ahead. It is part of the 20th-century material revolution which began with wireless, the automobile, and aspirin, and is now whirling through plastics, antibiotics, and atomic energy. Every invention, every new scientific application, in time transforms the conditions of human life, but it needs the shock of a new word to make people suddenly stop and consider where they are heading. Living from year to year and without a natural sense for recent history we quickly take for granted daily television, fresh foods out of season, the world's crises in the evening paper, and women at work in industry and the professions—as if they had been always so. Prof. LESLIE BANKS, in the paper on Industrialisation and Community Living, which we published on Feb. 4, said that Britain now has nearly a quarter of a million nurses and almost as many women teachers, and that the employment of men and women as clerks and in the distributive trades, in engineering and in chemicals, has greatly expanded in the last twenty years, while fewer are engaged in basic work like agriculture or coal-mining. "Two hundred years ago," the *Manchester Guardian*[1] remarks, "it took the efforts of every able bodied man to maintain a standard of living we would now call poverty. The Industrial Revolution changed that by making possible an enormous increase of individual productivity. . . . If instead of having 700,000 men dig 220 million tons of coal a year we generated the same amount of energy in nuclear power stations of the first crude design, less than 100,000 men would be needed."

Technological progress has been abolishing jobs for at least a couple of centuries, and creating fresh kinds of work also. What is new today is the speed of change, measured in fractions of a working life-time, and the numbers of people affected, in a society too highly organised to give the individual a free choice of occupation. A subcommittee of the United States Congress which recently reported on Automation and Technological Change,[2] thought that industry should provide organised re-training for workers, as well as financial compensation for the change of skill, and possibly change of abode, which the new work required. It recommended the government to collect statistics of occupational mobility, and to awaken people to the problems besetting their future employment, including the trend to larger impersonal businesses, the training of the elderly, and the threatened shortage of technicians and teachers of science in schools. Certainly if these problems are not solved we may expect unemployment and labour unrest as well as individual physical or mental breakdown. Modern industrial society already finds it harder to offer satisfactory employment to the dull, who need as much as other men to feel a sense of purpose in the community and to have an outlet for their creative urges. Mental hospitals already receive patients whose practical trouble is failure to find a satisfactory niche in life because their personalities belong to one of the minority groups, while modern society is planned more and more to suit the majority who cluster round the mean. A society which creates misfits needs advice on mental hygiene.

Professor BANKS raises also the problem of increasing leisure. He suggests that people might prefer to work a 60 hour week with 13 weeks' annual holiday rather than a 40-hour week with a fortnight, and the immediate value of this idea is its challenge to the present conventions of off-time. After all, the plan of resting the seventh day of every week was an invention of Semitic races, not practised in classical Rome or in other ancient civilisations. The British country-house classes expanded it into the weekend which everyone now expects; but habits can be changed. If health and output were the sole consideration (which they are not) it might be better to have one day off in every four, in some kinds of work anyway, rather than two at the end of every week. But it is noteworthy that the Soviet Union, having tried such an arrangement, has returned to a weekly rhythm.

[2] Report of the Subcommittee on Economic Stabilisation of the Joint Committee on the Economic Report. United States Government Printing Office, Washington, 1955.

Since the new regulations were introduced in 1952 no clear definitive statement has been made on this point The problem of tuberculosis is still not receiving the immediate and earnest attention that it should If routine annual tuberculin testing of all school children, with the tracking down of the source case in tuberculin positive cases, radiographic examination of all hospital cases, both inpatients and outpatients, radiographic examination of immigrants, vagrants, and especially of selected age groups such as men over 45, were carried out there would be an appreciable rise in the notification rate, and also a slight rise in the mortality figures All this would suggest that we were gradually getting to know more about the level of tuberculous infection in the community and make us realise that not only is the problem great but we are still a long way off the solution

KENNETH MARSH

ACUTE MASTITIS

SIR,—With reference to Dr Mavis Gunther's article (Jan 28) I should like to make the following observations

> "Attempts to find an organism failed on the five occasions when blood was taken for culture as the temperature rose", but bacteriological examination of the secretion from the affected gland would be more logical, on account of the fairly effective milk-blood barrier
>
> Intramammary antibiotic therapy through the nipple or otherwise into the secretion may be very effective by providing a high concentration of the substance where it is most needed

In the cow there is little risk of mastitis with cessation of milking, provided a long acting antibiotic, such as procaine penicillin in oil (as little as 100,000 units every two days for a week), is introduced into the teat canal as a prophylactic There is abundant evidence that in the cow 100,000 units of sodium penicillin administered through the teat canal daily for four to five days will give excellent results in acute streptococcal mastitis, usually clinical cure results in twenty four hours, and bacteriological cure in three to four days Bovine staphylococcal mastitis is not so responsive, but unless intramammary antibiotic therapy is used the prognosis may be poor

Chwilog, Caernarvonshire

T HUGHES ELLIS

POLIOMYELITIS

SIR,—I have read Mr Daw's letter (Jan 21) with great interest

Last term my five year old daughter started going to the council infants' school After about three weeks she developed a cold, so I decided to take her but to have a word with her class mistress As it happened, I met the headmistress, and to my surprise she said she would much prefer the child not to come until the cold had cleared

Later that morning I received a visit from the sanitary inspector, who asked why my daughter was not at school I explained When he murmured something about polio which I did not hear correctly, I said, "Well I suppose it's possible although it looks like an ordinary cold, but why pick on us?" He looked astonished and said, "But didn't Miss—— tell you? A child in your daughter's class has polio That is why she asked you to keep her at home"

I decided not to send my daughter back to school for at least a week Meanwhile, I received a daily telephone call from the sanitary inspector's office to inquire about her health During the first of these telephone calls I asked whether this secrecy was council policy, but was assured that it was entirely a matter for the headmistress to decide

Later I visited the officer in charge of infants' education in the borough, which is in London It was perfectly clear from his reaction that it is the policy of this council to keep all knowledge of poliomyelitis as close a secret as possible He said that, had I asked the headmistress point blank if there was polio in the school, she would in all probability have said No He attempted to justify this extraordinary attitude by saying that parents would be frightened and keep their children away if they knew

Now, personally I find it reasonable to be frightened of poliomyelitis, and clearly I am not alone in this, because at the same time a reputable public school circularised the parents when they had one or more cases

Surely it is quite wrong to suppress a thing of this nature After all, one takes quite a different view of a cold if it is known that the child has been in contact with a case of poliomyelitis, then one can at least prevent it from making further contacts Secondly, it is folly to think that such things can be *kept secret* As Sir Winston Churchill well knew there is much less danger of panic if people are told bad news by authority than if they find it out through distorted rumours

M E C BLACKLAY

"MUNCHAUSEN'S SYNDROME"

SIR,—A man corresponding to the one described in previous letters[1] was seen in the casualty department on Feb 2 Clinical and radiographic findings were identical with those reported by Dr Baker (Jan 28) He complained of severe headache and giddiness and ataxia He denied ever having been a seaman and gave his occupation as vocalist and mental nurse On being offered analgesics and the services of a psychiatrist he left the hospital with some indignation His ataxia was observed to have disappeared when he reached the street This patient had previously been seen here on May 30, 1955, with a story that he had been admitted unconscious to Queen Adelaide Hospital, Dublin, five days previously and had undergone a radical mastoidectomy there At that time he had a right facial palsy

Middlesex Hospital
London W 1

A O ROBSON

THE EPIDEMIOLOGY OF LUNG CANCER IN NEW ZEALAND

SIR,—Dr Eastcott (Jan 7) is to be congratulated on a first class contribution to the study of the ætiology of lung cancer Dr Joules (Jan 21) is rather critical, but completely fails to present any evidence to justify such remarks as "Dr Eastcott has failed to note the scientific evidence from many parts of the world that there is a causal relationship between the number of cigarettes smoked and the incidence of this disease"

The death-rate from lung cancer among males aged 45-54 years is almost three times as high in this country as in New Zealand Are we to conclude, from what Dr Joules says, that this is due to the fact that the former group has smoked three times as many cigarettes, on the average, as the latter group? It seems rather unlikely But supposing it were so, it must follow that pipe smoking is a relatively harmless pastime, for the total consumption of tobacco per head is about the same in both countries, so that the inhabitants of New Zealand must have smoked three times as much pipe tobacco as the average Englishman Would Dr Joules agree with this view?

Dr Eastcott has not only demonstrated large differences in the incidence of lung cancer between native born New Zealanders and immigrants from the U K, he has also shown large differences in the latter group—between those who left the U K when under 30, and those who left after that age Perhaps Dr Joules could give some cogent reasons for expecting a difference in smoking habits between these two groups

It would be foolish to deny the existence of a relationship between smoking and lung cancer, but it seems equally foolish to insist that this is the only factor involved, especially in view of a recent paper by Stocks and Campbell[2] Some towns in England, for instance, have twice as much lung cancer as others It is unlikely that the inhabitants of the former towns smoke twice as much as the inhabitants of the latter These observations, it seems to me, are not at all incompatible with the idea of some sort of synergistic effect between smoking and air pollution

London N 7

J TORRANCE

SIR,—I should like to correct a misunderstanding by Dr Joules (Jan 21) of my article He says I have "failed to note the scientific evidence from many parts of the world that there is a causal relationship between the number of cigarettes smoked and the incidence of lung cancer" This is not true I have followed this work with the greatest admiration, and in particular I regard the work of Doll and Bradford Hill as a classical study that will stand out in history like that of such men as Snow, Budd, Ross, and ing[10, 11] and trials in Germany and Austria have shown its value by mouth, particularly in children[12, 13] It may be that many of the infections that have been treated with penicillin parenterally in the past may now be treated with penicillin V orally In conditions in which higher blood-levels are needed (bacterial endocarditis, for example) the simultaneous administration of probenecid is an advantage[8]

---

[1] *Lancet*, Jan 14 1956 p 107 *Ibid*, Jan 21 1956, p 160 *Ibid* Jan 28 1956 p 207

[2] Stocks P Campbell J M *Brit med J* 1955, ii 923

At the Annual Symposium on Antibiotics held in Washington last November a speaker from Sweden said that 40% of the penicillin used in his country was now in the form of penicillin V tablets, and another speaker said that in Austria 30% of all the penicillin administered was given as oral penicillin V The drug has now been available in this country for several months

STAPHYLOCOCCAL INFECTIONS AFTER CARDIAC SURGERY

Postoperative sepsis is more common than is generally supposed, and, in spite of antibiotics, it may threaten the patient's life or at least his hope of a quick recovery In some branches of surgery particular attention has been given to the prevention of wound infection perhaps this is because the tissues concerned are especially liable to infection and because the results of sepsis after certain types of operation are unusually serious It is certainly true that the literature on this subject has been particularly concerned with intracranial, orthopædic, and plastic surgery and with the treatment of burns[14–17]

It seems that in the extending work of thoracic surgery similar problems are arising Operations on the lung are often complicated by staphylococcal infection of wounds and intrathoracic spaces[18] Fleming and Seal[19] now report 9 instances (5 of them fatal) of serious staphylococcal infection after operations on the heart or great vessels 7 of the operations were for mitral valvotomy and 2 for division of a patent ductus arteriosus An endocardial infection, demonstrated post mortem, was certainly responsible for 2 deaths and probably for 2 more Auricular fibrillation, associated with a myocardial abscess, was the cause of another death In the 4 surviving patients the clinical findings and positive blood-cultures suggested endocarditis Coagulase-positive *Staphylococcus aureus*, alone or in association with *Streptococcus viridans*, was the organism responsible in 6 cases It is particularly interesting that coagulase negative *Staph albus* was incriminated in the other 3 This organism was isolated from blood-cultures in each of these 3 patients, and in 1 it was also grown in pure culture from the mitral vegetations found at necropsy It was resistant to penicillin, and the patient's serum contained antibodies against it Fleming and Seal remark that failure to recognise the pathogenic rôle of *Staph albus* in this case led to inadequate treatment of the infection

Staph albus is a common contaminant and is often ignored when isolated from blood cultures There is good reason for the general belief that this organism is of lower pathogenicity than the related *Staph aureus* strains producing coagulase, but this is not to say that it cannot attack delicate tissues Bacteriologists who see a profuse and pure growth of *Staph albus* from cases of neonatal conjunctivitis may be easily convinced of this The susceptibility of the damaged endocardium to infection with *Strep viridans* suggests that this, too, is vulnerable to organisms of low virulence for other tissues, and it may well be that *Staph albus* can also cause endocarditis Fleming and Seal present good evidence, from their own work and from recent publications that this is so

They also discuss briefly the possible sources of infection in these 9 cases They believe that the chief risk was at the time of operation, although preoperative intravenous manipulations may have played a part They found that staphylococci were the main airborne organisms contaminating the surgeons' equipment and gloves, and these organisms may be introduced when a finger is put into the heart to dilate the mitral ring Another risk, not mentioned by Fleming and Seal, is that digital manipulations in a tight mitral valve probably cause extreme stretching of the glove rubber and may open minute holes through which organisms from the surgeon's skin can pass It has been shown that more than half the surgeons' gloves are punctured during lung operations,[18] and it would be interesting to know how often there is a puncture over the surgeon's finger after a mitral valvotomy With so many new materials about nowadays, something better than rubber could possibly be found for surgical gloves, but in the meantime thoracic surgeons might enclose the gloved finger in a freshly sterilised stall of some impervious plastic material immediately before putting it into the heart This might be preferable to Fleming and Seal's suggestion that prophylactic penicillin should be used to protect the patient against these infections

ANTICONVULSANT ACTION OF ACETAZOLAMIDE

Shortly after the introduction of the sulphonamides into clinical practice it was observed that sulphanilamide[20] and the dye 'Prontosil S'[21] were able to reduce the frequency of convulsions in some epileptic patients The sulphonamides are known to inhibit carbonic anhydrase[22] and thus produce acidosis, and it was thought that this acidosis was responsible for the anti-epileptic action, which was compared to the effect of the ketogenic diet Because of the toxicity of the earlier sulphonamides this observation was not widely explored Acetazolamide[23] provided a relatively non-toxic sulphonamide which was a powerful inhibitor of carbonic anhydrase, and it too has been used in the treatment of epilepsy in adults and children with, on the whole, favourable results[24–26] There may be side effects[24] and there are few cases in which acetazolamide is preferable to the standard anti-epileptic drugs On the other hand, one child whose epilepsy took the form of intense periods of hyperventilation was much relieved by acetazolamide[25]

Millichap and his co workers in the University of Utah[27] have studied the mechanism of the anticonvulsant action of acetazolamide in mice They confirmed that it prevented electrically induced seizures and was twice as effective in this way as sulphanilamide Acetazolamide was a hundred times more effective than sulphanilamide as an inhibitor of carbonic anhydrase Sulphathiazole, which does not inhibit carbonic anhydrase, did not prevent seizures in mice Millichap et al then found that both acetazolamide and sulphanilamide retained their

in his tortuous aorta, both on postero anterior and lateral views, completely consistent with atheroma

This finding, however, is not at all inconsistent with the theory that was proposed for the pathogenesis of atheroma formation, since the blood of hæmophiliacs obviously does clot, even if it takes longer than normal blood, and even though this patient did have a prolonged clotting-time (41 minutes), he had had 67 years to lay a little fibrin down on his aorta

I am grateful to Dr Benjamin Jacobson for allowing me to describe this case

Massachusetts General Hospital,
Boston 14, Mass, U S A JOHN R DAVID

INGUINAL HERNIORRHAPHY

SIR,—The "anatomical proof" by Mr Doran (Dec 24) of the inability of the conjoined tendon to act as a sphincter or shutter in relation to the inguinal canal seems to me to be built up on a false premise He takes a point on the linea alba below the umbilicus and claims that it cannot move in the long axis of the body so long as the sternum and pubis remain the same distance apart From this assumption he deduces that the conjoined tendon cannot shut down on the spermatic cord

The fallacy is that the linea alba is elastic, its length in the extended position of the trunk being at least 50% greater than that in the flexed position It is therefore illogical to claim that any point on it can be regarded as fixed, and it would be quite possible for points on its lower half to move towards the pubis on contraction of the abdominal muscles Much depends on the direction and power of the muscle fibres inserted into the linea alba, and it could be argued that since the pyramidalis muscles are the only ones which act almost parallel to the linea alba they will tend to pull down its lower part towards the pubis

Mr Doran may be correct in his claim regarding the absence of a shutter action, indeed, his own observations with radio opaque markers support this view But although he affirms that the lower fibres of the internal oblique muscle appear to run almost parallel to the inguinal ligament the anatomical insertion of the conjoined tendon is undoubtedly in part into the pubic crest and pectineal line, and fibres from the internal oblique and transversus abdominis arising from the inguinal ligament cannot reach such an insertion without arching over the spermatic cord Now, if the arched fibres of the conjoined tendon shorten when they are stimulated—and there seems to be no reason why they should not—their course must become straighter and this can only happen by their approximating more closely to the inguinal ligament

Manchester HERBERT HAXTON

DOMICILIARY CONSULTATION IN PSYCHIATRIC PRACTICE

SIR,—The problem of the community care of mentally disabled persons referred to by Dr Skottowe (Jan 28) has been partially solved in Holland by the establishment of sheltered workshops in some of the larger towns I recently visited one of these workshops in the Hague, and was most impressed by the way in which both mentally ill and mentally defective patients were gainfully employed This workshop has already been briefly described by Carstairs et al [1]

There are obvious disadvantages in mixing psychotic and defective patients, and plans have already been made for building new workshops where the two types of patient will be separated At present 290 patients (out of a total population of 600,000) are employed The staff consists of a works manager, 6 technical assistants, 7 nurses, and 3 clerks The whole enterprise is under the direct supervision of the city psychiatrist, Dr N Speyer The patients work a 48 hour week and are paid 40–80 cents per hour according to ability and output The "normal" factory worker is said to get 90 cents to 1 florin per hour (1 fl =2s approx)

Work is sent in from local factories, which also lend some of the necessary machinery and collect the finished products The work done includes making cardboard boxes, packing chocolates, machine riveting boxes, making articles of clothing with electric machines, assembling brake cables for mini motors, and book binding The patients live either in their own homes or in hostels and come to the factory by public transport, as the mentally ill patients improve they are found jobs in outside factories Psychiatric supervision is maintained by the department of mental health of the municipality of the Hague

If something of the same nature were to be started in this country there would be need for close collaboration between the local authorities and the regional hospital boards, but it would be a great pity if so potentially valuable a project were to be abandoned because of administrative difficulties By the use of such sheltered workshops not only could many patients be kept out of hospital but many of those now more or less permanently resident could be discharged with benefit to themselves, through prevention of deterioration and improvement in morale, as well as to the country as a whole by reducing the burden on the health service and helping in the production of goods

London, W 1 J C SAWLE THOMAS

"ESPRESSO WRIST"

SIR,—As far as I am aware no social medicine study has been made of the possible effects of the coffee bar epidemic which has swept London since the war A few visits will serve to convince an observer that there is much to discover both amongst those who serve and those who meet to drink Meanwhile, anyone who is contemplating such a survey is offered the information of an interesting orthopædic complication—"the espresso wrist"

de Quervain [1] described stenosing tendovaginitis at the radial styloid as long ago as 1895, and we are used to seeing cases amongst young mothers engaged in unaccustomed nappie wringing, seamstresses working overtime for the Christmas season, and high speed obsessional typists To these we can now add the espresso machine operator For each cup of coffee he has to carry out three to four strong movements of the wrist into full radial deviation, and in an average day may carry out several thousand similar manœuvres (Barmaids are no doubt immune because the beer is pulled with wrist held stiffly, the elbow being flexed)

Fortunately the acute condition responds readily to one or two well-placed injections of hydrocortisone and a slight change of technique, and the counter attack by the tea drinkers—we are told—is already well under way

London W 1 A W LIPMANN KESSEL

ECLAMPSIA

SIR,—I am grateful to Dr Schuurmans for his informative letters (Dec 17 and Jan 21) The information he supplies conforms with my ideas on eclampsia

In Holland, during the war, eclampsia almost disappeared with a low protein, low carbohydrate diet, which bordered on starvation In the Belgian Congo, among two million natives living on an "inadequate diet," also presumably of low protein and low carbohydrate content, not "a single case of toxæmia has ever occurred" (What a wonderfully thorough system of antenatal care they must have in the Congo to be able to report this!)

On the other hand, in Australia Hamlin has eradicated eclampsia with a high protein, low carbohydrate diet Clearly eclampsia disappears in spite of, and not because of, a high or low protein intake, but high protein intake is to be recommended because it helps to abate hunger when mothers are only eating little carbohydrate Equally clearly, in all three groups, it is the low carbohydrate intake which is the vital factor in preventing eclampsia and toxæmia

Coloured women in the Southern States of the U S A, eating relatively more carbohydrate, suffer, despite "the same antenatal care," much more commonly from severe toxæmia than do white women, who are eating more protein and (presumably) relatively less carbohydrate, in the Northern States But no antenatal care will prevent toxæmia if the diet is faulty—i e, if the carbohydrate is excessive The "care" merely observes the effects of the toxin on the mother and tries to palliate them, having waited for the toxin to be produced before it acts Production of toxin, as I said (Nov 5), can only be prevented reliably by controlling diet, appetite, and weight

If only the suicidal saying "eating for two" could be forgotten, and if a new motto, "eat starchy foods sparingly,"

UNDERSTANDING THE DEPRIVED CHILD*

PHILIP PINKERTON
M B Edin , D.P M
CONSULTANT PHYSICIAN IN PSYCHOLOGICAL MEDICINE,
ALDER HEY CHILDREN'S HOSPITAL, LIVERPOOL

MANY children who are deprived of a normal home life find it difficult to adjust to their altered circumstances They have to cope with new and perhaps frightening problems which have arisen from the breakdown of their family life, and they need help I am convinced that, however efficient the organisation for taking them into care, and however comprehensive our legislation to safeguard their welfare, we really begin to help them only when we get down to understanding the individual child and his problems

There is something oddly uniform in the manner and behaviour of these children As the following examples show

An 11 year old girl, who has been in care since the age of 2, is described as " sullen, reticent, and suspicious At times she is very destructive She has frequent outbursts of violent temper, and her behaviour in general is unpredictable "

A 9 year old boy, who has lived in several residential homes and for a time with foster parents, is described as " aloof and taciturn, solitary and resentful He had been caught stealing money from the foster home on several occasions and always lied blatantly about these thefts They had never succeeded in overcoming his aloofness He was always mistrustful and wore 'a chip on his shoulder ' If reprimanded, he would have a temper tantrum "

It is true that not all deprived children behave in this way, and it is equally true that by no means all children with such conduct disorders are technically deprived , but it is a recurring pattern among deprived children Why do they behave in this way ? Why are they so aloof and sullen and moody ? Why is it so difficult to get close to them ? Why are they so suspicious and unresponsive ?

BACKGROUND OF DEPRIVATION

During his formative years a child, whether deprived or not, has certain basic needs, including adequate nourishment, clothing, and shelter Equally vital is the child's need for constant affection, and for a feeling that he belongs securely within a family group. In the early years of life, this demand for affection is fundamental It is also highly selective, because it is the love of his mother that the child needs, or, in default of the mother, a substitute but constant mother figure

When young children are sent to hospital they are usually separated from their mothers, though only temporarily and usually for a short time While in hospital, they receive expert and kindly attention , yet, unless we take precautions some of them will so miss the indispensable relationship with their mothers that they will fret and show emotional upset Some fret openly and are inconsolable in their tears Others fret inwardly, becoming quiet and withdrawn, and morose

If normal young children can be adversely affected by a temporary loss of contact with maternal warmth and security, how much greater must be the effect on the deprived child whose loss is lengthy or permanent Consider how such a child must feel His security may already have been undermined by the disrupting influence of a broken home He may be struggling to overcome an engulfing wave of grief, from the death of a parent He may be confused, and bewildered in his loyalties, by the desertion of a feckless father or the defection of a deficient and selfish mother He may have been rejected and cast out at birth as an illegitimate and unwanted child, so that he has never known the warmth of maternal affection or the security of belonging within a family unit Often, such a child has suffered repeated rebuffs from parents or guardians, who have rejected him, sometimes shamelessly, or perhaps neglected him in ways more subtle but equally damaging When he comes into care, he appears withdrawn and unresponsive His feelings may have been hurt so many times that he has learnt to protect them by a taciturn and sullen mask

Many of these children have been let down again and again by unreliable parents, or misled repeatedly by false promises They feel suspicious and mistrustful of adults Our assurances, given in good faith, may have been heard before by the child, when they were not fulfilled How can he feel sure that this time he can accept them ? His suspicions and hostility, his withdrawal and moodiness, are surely understandable

Slowly, however, we overcome his suspicion and we think he is beginning to trust us and give his confidence to us Many of these boys and girls do respond in this way , but to our dismay—and even, let it be said, to our righteous indignation—there are some who bite the hand that feeds them, who repay kindness with aggression, and who take advantage of our tolerance by abusing privileges and by provoking disturbances How can we explain this phenomenon ?

When I am trying to pacify outraged foster parents, who complain bitterly about this sort of behaviour, I ask them to imagine that for years they have had to use a bridge to cross a dangerous river which separates their house from their shopping centre The bridge is solid and they have long since lost any qualms about committing their safety to it Then one day, during a violent storm, the bridge is struck by lightning while they are crossing and they are pitched into the water The experience is highly unpleasant When they have recovered, and resume their daily journey, they find a new bridge in place of the old one It looks unfamiliar, not as solid or secure as the original one, and they naturally feel some misgivings about committing their weight to it They could hardly be blamed if, as a precaution they were to test the stability of the bridge beforehand, by shaking it or perhaps kicking it, and only when they were satisfied that it could stand such punishment would they feel safe about crossing

These difficult children have been subjected to one upheaval after another and they have become understandably wary We, in our turn, set ourselves to convince them that they can safely open up their badly wounded feelings to us But the child must be sure of his support before he does so He is perhaps near the end of his emotional tether, and to be let down again might mean complete emotional breakdown Almost unconsciously, therefore, he is driven to test the support which is offered to him before he commits himself to it, and this is the basis of his provocative behaviour If he is loved while he remains cooperative and obedient, will he still be accepted when he is naughty and disobedient ? No child (or adult) likes to feel that he is loved, or that he is wanted, only on a selective basis We all like to feel that somewhere there is a place where we belong and where we will find unstinted affection, no matter how badly we behave

These children are groping blindly to achieve this aim And the only way they can allay their gnawing suspicions is deliberately to provoke adverse circumstances, so that they can judge the reaction of those who promise security If they are accepted when they are badly behaved, they can, they feel, safely put their trust in the security offered

NAUGHTY OR WITHDRAWN

As I have said, not all deprived children behave in this way For that matter, not all young children who are

Notes and News

WORLD HEALTH ORGANISATION

The Executive Board of the World Health Organisation, whose 17th session opened in Geneva on Jan 17, under the chairmanship of Dr Sabeeh Al-Wahbi (Iraq),[1] has recommended a budget of $11 million for the Organisation in 1957 This represents an increase of $800,000 over the current budget The board unanimously resolved that the time is ripe for large scale campaigns against leprosy in every country affected by the disease The board also decided that W H O should assume responsibility for coördinating and stimulating research into resistance to insecticides Dr M G Candau, director-general of W H O, declared "Should the degree of resistance in vectors of diseases such as malaria, yellow fever, plague, and typhus reach the point where control by the available insecticides is no longer possible, disastrous results from a health viewpoint will inevitably occur in many parts of the world" The board asked the director general to explore the possibility of organising centres for the histopathological examination of cancer tissues

WELLCOME TRUST

The Wellcome Trustees have announced two further awards They have made a grant of £80,000 to the Postgraduate Medical School of London, at Hammersmith, towards the cost of building and equipping laboratories for experimental research bearing upon problems of surgery The new laboratories will form part of the department of surgery, of which Prof Ian Aird is director Another grant goes to McGill University, Montreal, of $140,000 (approximately £50,000) to enable a Wellcome research professorship in anæsthesia to be created in the medical school The grant provides for the stipend of the chair and the research expenses of its department for five years, and for the initial equipment of its laboratories

PRESCRIPTIONS FOR POTASSIUM SALTS

Boots Pure Drug Co Ltd inform us that, with the more widespread use of cortisone and its allied steroids, doctors are prescribing potassium chloride in tablet form in order to combat hypokalæmia Prescriptions are being handed in at chemists' shops for tab pot chlor, but such an abbreviation is not used in the *British Pharmacopœia*, so there is some confusion as to whether potassium chlorate or potassium chloride is intended Messrs Boots have now asked their branches to be particularly careful over this point, and have suggested that it is the chloride which is more likely to be required than the chlorate The company remarks that, since internal administration of potassium chlorate may be dangerous, doctors should use the official terms—tab pot chlorid or tab pot chloras

A DEFENCE OF MASS RADIOGRAPHY

Prof A P Thomson, speaking to the Birmingham Regional Hospital Board on Jan 16, rebutted three criticisms of mass radiography—that it is expensive, that it leads to errors in diagnosis, and that it tends to make doctors neglect the clinical examination of their patients There could, he said, be no doubt about the value of the service in the Birmingham region the report of the Regional Director showed that in 1954, mass radiography revealed no fewer than 1357 patients with acute tuberculosis, 556 of whom had tubercle bacilli in their sputum Mass radiography was responsible for more than a third of all notifications of respiratory tuberculosis in Birmingham

The aim of mass radiography was not to make diagnoses but to discover abnormalities such as a "shadow" which required further investigation the diagnoses were made by physicians to whom the patients were referred Though sometimes a patient was told about a "shadow on the lung" which later was shown to be of no significance, any distress caused did not last long, and this small disadvantage was more than offset by the protection the service gave to the public, and to the reassurance it afforded those people who needlessly feared that they had tuberculosis

Among the patients in the Birmingham area examined by mass radiography in 1954, tuberculosis was found nearly seven times more frequently in those referred by general practitioners than in those in all the other groups The suggested that doctors did not neglect to examine the patients before referring them for radiography

Far from being expensive, the average cost of the mass radiography service for each person in the Birmingham region was 3d a year, which was cheap for a service which was in effect an important branch of preventive medicine Dr Thomson maintained that, at the present time, mass radiography afforded one of the best means of reducing the incidence of tuberculosis, by detecting it in its early stages and thus allowing infected patients to be isolated and treated promptly

OUTPATIENT DEPARTMENTS IN SCOTLAND

In 1954 hospital authorities in Scotland surveyed waiting times at outpatient departments On the basis of the information thus collected, and of other reports, the Secretary of State for Scotland has issued a memorandum[1] on the organisation of outpatient departments

Outpatient departments, says the memorandum, should be organised on the assumption that the present demand will be maintained or will increase Of 162 hospitals and clinics reported on, 93, with outpatient attendances estimated at 3,140,000 a year, had appointment systems for all attendances except casualties and self referred patients, 36, with 3,420,000 attendances, had appointment systems for more than half of their attendances, and 33, with 430,000 attendances, either had no appointment system at all or had one for less than half of their attendances Those hospitals or departments where an appointment system is in operation have much the lowest average waiting times It is clear that such systems are practicable in all specialties, and "where the operation of an appointment system is accompanied by a lengthy waiting period for appointments the fault is not the appointment system but the inadequacy of the department" Wherever possible a system of individual rather than block appointments should be used

COST OF INPATIENTS IN SCOTLAND

The average cost of maintaining a patient in hospital in Scotland, excluding the cost of the specialist service and overhead charges for empty beds, was £8 7s 3d a week in the year ended March 31, 1955, according to the annual analysis of the running costs of Scottish hospitals[2] This average was made up as follows

	£	s	d
Staff salaries and wages	4	5	2
Provisions	1	9	0
Drugs, dressings, patients clothing bedding &c		13	6
Domestic repairs laundry heat light, power &c	1	1	7
Overheads including maintenance of buildings and grounds		13	0
Board of management administration		6	0

The average weekly costs of maintaining and treating a patient in the different types of hospitals in 1954–55 were

		£	s	d
General	major teaching	12	8	1
”	over 300 beds	11	12	4
”	51–300 beds	12	0	10
”	1–50 beds	9	18	[illegible]
”	chronic sick	7	5	8
Convalescent hospitals and homes		8	8	7
Isolation hospitals		6	12	0
Sanatoria		9	3	0
Isolation and tuberculosis hospitals		10	0	2
Maternity hospitals and homes		15	11	1
Mental hospitals		5	0	10
Mental deficiency institutions		4	12	3
Other hospitals		9	10	0

The average cost of treating each outpatient was 5s per attendance

RESEARCH ON TRACHOMA IN THE MIDDLE EAST

A virus laboratory is being built in Jordan by the Order of the Hospital of St John of Jerusalem for research on the virus of trachoma, which, it is estimated, affects a quarter of the world's population and causes more visual disability and blindness than any other disease Sir Stewart Duke Elder, the hospitaller of the Order, said on Jan 30 that it was hoped that the laboratory would be working by the end of March under the direction of a research team consisting of a clinician a virologist, and a bacteriologist

Until recently, Sir Stewart said, trachoma was treated by cauterisation by copper and other metals—the kind of treatment used four thousand years ago Antibiotics have

REMUNERATION OF DOCTORS

IN GENERAL PRACTICE AND IN HOSPITALS

We have received the following letter:

Sir,—The rise in the cost of living hits everyone in the country, but does not affect different classes of the community equally. Wages and many salaries have, by and large, fully kept pace with this rise. Some fortunate people have been able to offset the combined incidence of declining money values and high taxation by appreciation in capital values. Others have not been so fortunate. Amongst the worst sufferers are those whose incomes are determined and changed infrequently, and doctors, the great majority of whom are now remunerated almost entirely from public funds, fall into this group.

The cost of living has risen steeply since 1950 and the real value of the incomes of general practitioners and hospital medical staffs has declined. The medical profession during these difficult years has been reluctant, in view of the national situation, to draw attention to its own financial position. It is, however, now compelled to claim from the Government increased remuneration for both general practitioners and all grades of hospital medical staff. A detailed statement setting out the background of the case accompanies this letter.

When Parliament introduced a State provided National Health Service, it thereby assumed the responsibility for maintaining an adequate standard of living for the doctors who play an essential part in it. What we are now asking is not merely that the value of professional remuneration should be restored, but the recognition of this responsibility in principle and its embodiment in policy.

A. Talbot Rogers
Chairman
General Medical Services Committee

W. Russell Brain
Chairman
Joint Consultants Committee

Statement

So far as the medical profession is concerned, the basis of remuneration in the National Health Service has been, and still is, the two Spens reports which were accepted by the profession and the Government. The Spens Committees framed their recommendations in terms of 1939 values of money, and, to quote from the General Practitioner report, "left to others the problem of the necessary adjustment to present conditions, observing that such adjustment should have direct regard, not only to estimates of the change in the value of money, but to the increases which have in fact, taken place since 1939 in incomes in other professions." A similar safeguard was included in the Consultant Spens report.

In the field of general practice there has been no "adjustment" since 1950. It is true that since the Danckwerts award the method of calculating the Central Pool safeguards the level of income in so far as practice expenses and the number of doctors taking part in the Service are concerned, but this takes no account of variations subsequent to 1950 in the betterment factor, which is still assessed at the level of 100% over 1939. This level is certainly an unrealistic figure today.

In the hospital service, although medical staff are now remunerated under a later award of 1954, they are in the same position, as they too have received no increase in the betterment factor since 1950. During the negotiations which led up to the 1954 award, the Government refused to accept any claim based on betterment, and the settlement which was reached was on the ground that the Danckwerts award had disturbed the relativity between general practitioners and consultants (previously established by the two Spens Committees) and that an increase in consultant remuneration was necessary to safeguard recruitment to that branch of the profession.

Since the Danckwerts award established a betterment factor of 100% for general practitioners in 1950 and the consultant award of 1954 restored the balance between the two branches, it follows that the remuneration of both sections, in so far as the betterment factor is concerned, was stabilised as at 1950. To put it another way, general practitioners and hospital medical staff are now remunerated at rates which, so far as values of money are concerned, are related to the year 1950 and any adjustment to offset changes which have occurred since that date must apply to both branches of the profession.

In the past, negotiations in the field of remuneration have been carried out independently by the General Medical Services Committee of the British Medical Association, representing general practitioners, and by the Staff Side of Committee B of the Medical Whitley Council, representing hospital medical staff. This was perhaps inevitable because in previous claims the factors in dispute were not common to both fields. The present issue is, however, straightforward. It is that the existing rates of remuneration must be adjusted to meet the decline in the value of money since 1950. Since both branches are affected by this decline there is every advantage to be gained from a joint approach to the Government. Experience has shown that any claim submitted on behalf of one section of the profession would be examined by the Ministry not on its merits alone but also on its possible repercussions in other fields of practice.

These matters have been carefully considered by the General Medical Services Committee and the Joint Consultants Committee, and both feel that, with a continuing inflationary trend and in the light of the increases afforded to or claimed by other sections of the community, they have no option but to take immediate steps to remedy the disadvantageous position in which general practitioners and hospital medical staffs now find themselves.

Both committees are equally convinced that it is in the best interests of all that a joint claim should be made with the full weight of the profession behind it. This view has been endorsed by the council of the British Medical Association and by the Joint Consultants Committee.

In consequence the Minister of Health has been informed by the General Medical Services Committee of the British Medical Association, representing general practitioners, and the Joint Consultants Committee, acting on behalf of all grades of hospital medical staffs, of the intention to submit an early claim for an increase in the betterment factor.

The preparation of the joint claim is now under way and for this purpose a Joint Negotiating Committee of the two bodies has been set up under the joint chairmanship of the chairmen of the General Medical Services Committee and the Joint Consultants Committee. It will be assisted by Prof. R. G. D. Allen, D.SC., professor of statistics of the University of London, whose evidence played an invaluable part in the Danckwerts adjudication.

The Public Health Committee of the British Medical Association has been kept informed of these developments, and its chairman has been invited to be present at the meetings of the Joint Negotiating Committee referred to above.

It will be appreciated that the submission of a precise claim must depend largely upon the availability of accurate statistical information and we are advised that this will not be ready until the end of April. In the meantime all the necessary preparations are in hand.

Finally, it is wished to emphasise that this is not a claim for new money. Indeed, it is not a claim for anything more than the remuneration which the Spens reports laid down to be proper for the medical profession. The decline in the value of money has meant that the profession during the last five years has not received what was regarded as its due when the Spens reports were accepted by the Government at the inception of the National Health Service. What is asked is that this obvious injustice should now be made good.

A Medical High Commissioner

The Queen has appointed Mr Walter Elliot to be High Commissioner to the General Assembly of the Church of Scotland, *which meets in Edinburgh on May 22*

Society of Medical Officers of Health

Sir Selwyn Selwyn-Clarke has been appointed medical secretary of this society in succession to Dr Frederick Hall Sir Selwyn has held the posts of director of medical services, Hong-Kong, and chief health officer, Federated Malay States, and since his retirement from the governorship of the Seychelles he has been a principal medical officer at the Ministry of Health

Shortage of Mental Nurses in Lancashire

At the opening in Manchester of an exhibition intended to promote the recruitment of mental nurses, protests were made by the staff of local hospitals against their pay and conditions The *Times* (Jan 31) reports that 60 pickets paraded with sandwich-boards At the opening of the exhibition Mr N M Agnew, chairman of the Manchester Regional Hospital Board, said that, subject to the General Nursing Council's approval, his board was to introduce a four year course for student nurses to spend part of their training at a general hospital and part at a mental hospital

Changes in Industrial Injuries Benefits

The Minister of Pensions and National Insurance has accepted two recent recommendations by the Industrial Injuries Advisory Council (Cmd 9673 and 9674) The changes came into force on Feb 8

The conditions for payment of industrial injuries benefit for byssinosis are to be relaxed The period of qualifying employment in the cotton industry has been reduced from 20 years to 10 years, and the present condition that benefit cannot be paid unless the disablement is assessed at 50% or more has been removed

People whose occupations involve exposure to cadmium fumes are now to be insured under the Industrial Injuries Scheme against chronic as well as acute, cadmium poisoning

Special Times for Certificates ?

Doctors in large urban parishes in the Doncaster area are to be asked to consider a plan for reducing overcrowding in their surgeries Doncaster public health committee suggest that there would be more room for patients requiring treatment if special times were allocated to those wanting sickness certificates only , one proposal is that doctors might set aside half an hour at the beginning or the end of the normal surgery hours for dealing with certificates Dr R W L Ward, public-relations officer to the Doncaster division of the British Medical Association, is reported to have said that, in his opinion, most doctors would oppose any such distinction between patients

herefore, that together with a work-therapy project, uch as we have started at Banstead, we shall also need o have hostel accommodation in our catchment area, ear to centres of industry, where patients who have left hospital can live

Even in the past year our increased interest in long stay patients and their problems, together with active treatment programmes for them, has shown that a considerable proportion can become well enough to leave hospital We feel that with the new techniques available we shall be able to discharge these patients much faster than was possible in the past, and that the large buildings and overcrowded wards which we have known for so many years will then become obsolete It would not seem impossible, in a hospital of this size, to discharge long stay patients at the rate of 100 a year, and this would mean that in twelve years the patient population at Banstead could be halved To build new hospital accommodation would seem unnecessary, and the old buildings we have, though unsatisfactory in so many ways, can be put to good use The large barn-like wards, which have been so seriously criticised of late, may find a fresh function Perhaps, in the future, they may be adapted from custodial care to factory floor space At present we have one ward out of forty which is working as a factory perhaps in twelve years we could have twenty wards for factory use and twenty left for ordinary treatment purposes Some ex-patients would then return to hospital in the daytime for the sheltered factory employment they need

Although the symbolic walls around our mental hospitals are being removed and the gates opened, there are still barriers in the minds of the community We may be willing to discharge our patients, but this does not mean that the community is willing to accept them Psychiatric treatment should not be concerned only with the immediate care of the patient but should also consider the major social influences in the community at large In many of our difficulties there is the same underlying, and as yet unanswered, question Does the community wish to keep its mentally sick, for whom there is no immediate active treatment, locked away, with someone else responsible for their care, and financially supported ? Or is the community prepared to accept the long-term patient in its midst, self supporting, but an occasional source of embarrassment ?

I wish to acknowledge the help and encouragement given by Dr E P H. Charlton, physician superintendent at the hospital I also want to acknowledge the work and coöperation of the nursing staff

Public Health

Poliomyelitis Vaccine

An "aide-memoire" prepared by the Ministry of Health for the information of medical officers of health gives some further details about the poliomyelitis vaccine to be used in this country

The Salk vaccine used in the United States of America is made from a mixture of pools of the three known types of poliomyelitis virus grown in a special tissue-culture medium (Connaught no 199 medium) containing monkey-kidney tissue Animal serum is added during the growing-out phase of the culture This medium also contains penicillin and streptomycin, which during subsequent processing are to a great extent inactivated The cultures are filtered and the virus inactivated by formaldehyde, this inactivating agent being added to a final concentration of 1 in 4000 Three tissue-culture tests are made to determine the rate of inactivation The pH of the mixture and the temperature of the inactivation process are also carefully controlled A bacteriostatic agent, merthiolate, together with 'Versene,' is added to the vaccine Filtration before and at stages during the inactivation process are considered important steps in ensuring a safe vaccine by the removal of particulate matter The strains of the three known types of poliomyelitis virus used in Salk vaccine are type I, Mahoney, type II, M E F 1, and type III, Saukett

The Salk-type vaccines of the two manufacturers in this country are similar but the component strains of poliomyelitis virus are different In the Glaxo vaccine the strains are type I, Enders modification of Brunhilde, type II, M E F 1, and type III, Saukett (The types II and III in this vaccine are the same as those used in the Salk vaccine) In the Burroughs Wellcome vaccine the strains are type I, Enders modification of Brunhilde, type II, attenuated Y-SK, and type III, attenuated Leon Final formal approval has not yet been given in respect of strains type II and III used in the Burroughs Wellcome vaccine

On the subject of safety tests, the aide-memoire says

"During and after inactivation each monovalent bulk strain pool is tested for active virus by tissue culture methods Not less than two tests are made during inactivation at 37°C on samples of 500 ml taken at intervals separated by at least three days The consistency with which manufacturers obtain negative results in tissue culture safety tests on strain pools is a major factor in determining safety

"The final vaccine, prepared by pooling monovalent bulk strain pools which have passed the prescribed tests, is again subjected to test A sample of at least 1500 ml is tested similarly by tissue culture methods In addition a monkey safety test is applied to a sample drawn from the final containers This safety test is made on healthy rhesus monkeys which have been treated with cortisone to make them more susceptible to infection with poliomyelitis virus Each monkey is injected intraspinally and intracerebrally and is observed for 28 days when it is killed and histological sections are examined from the central nervous system The number of monkey safety tests made is determined by the number of filling lots of the batch of the vaccine "

The vaccine is also tested for the absence of other pathogens for man (e g, *Mycobacterium tuberculosis*, virus B, and lymphocytic choriomeningitis virus)

Antigenicity tests are made on monkeys and on mice Other rodents such as guineapigs, hooded rats, and cotton rats are being tried for this purpose

Theoretically," the aide-memoire continues, "in view of the presence of monkey kidney protein in the vaccine, sensitisation to it and the production of Rh antibodies are possible but the extensive use of Salk vaccine in other countries indicates that these theoretical possibilities are of little practical importance "

The W H O group which met last November "considered that the amounts of penicillin and streptomycin in the poliomyelitis vaccine were so small that the danger of sensitisation to these antibiotics as a result of vaccination was very small Nevertheless the possible effects of sensitisation and of vaccination in a sensitised person must be kept in mind, although no reactions of this nature have been mentioned in reports from official sources in the United States, Canada, and other countries which have supplied information on their experience with poliomyelitis vaccine "

'Where advice is asked as to whether other immunising procedures should be undertaken simultaneously with vaccination against poliomyelitis, it is probably reasonable to suggest the postponement of smallpox vaccination and other immunisation for at least a fortnight "

Parry of Bristol

For more than a quarter of a century Robert Hughes Parry has been medical officer of health for Bristol, and now he has gone to be visiting professor in public health at Yale before becoming (so he says) a farmer at Criccieth He came to public health after three years in cancer research at the Middlesex Hospital and a further three years in general practice in North Wales with his wife, Dr Joan Parry From that time onwards, there has been nothing dull in his conception or his practice of preventive medicine, for he has believed in things and has said so strongly, vividly, humanly He believes that "if it is to fight disease effectively, the medical profession as a whole needs in fact to be more than interested in the social services that are fighting the other giants of the Beveridge report —Want, Ignorance, Squalor, and Idleness, as well as tion in the urine with the patient's degree of consciousness When a large dose of a short-acting barbiturate, such as pentobarbitone, is taken by mouth, the blood-level reaches about 5 mg per 100 ml twelve hours after ingestion of the drug The level then falls fairly steadily and nearly all the drug is cleared from the body within four days Consciousness is regained when the level falls to between 1 and 2 mg per 100 ml When the poisoning is fatal, the blood-level at death may not be significantly higher than the level found in some patients who recover With comparable doses of phenobarbitone, the blood-level may rise to 10 mg per 100 ml, and consciousness tends to return when the level reaches 5–6 mg The level falls slowly with this drug and the blood may still contain 4 mg per 100 ml seven days after ingestion Barbitone is also excreted very slowly blood levels approaching 20 mg per 100 ml have been found twenty four hours after ingestion, while ten days later the figure was still 2 mg per 100 ml There is, of course, variation from patient to patient in the degree of consciousness associated with different blood levels of the drugs WRIGHT found that 2 patients who had been subject to epilepsy for twenty years remained conscious when the phenobarbitone level was over 5 mg per 100 ml, but such tolerance was unusual, and no patient was free from symptoms or signs of intoxication with a blood-level of over 3 mg per 100 ml Dr WRIGHT and Mr BROUGHTON and his colleagues have done an important service in exploring this new biochemical technique the clinician will be glad of biochemical guidance about which barbiturate was taken, how much, and when, since he so often lacks this information when it is most needed

We have as yet no means of hastening the destruction or excretion of ingested barbiturate The use of analeptics in barbiturate poisoning, favoured by some workers and rejected by others, is designed to keep the patient conscious or nearly conscious until the barbiturate has been dissipated A more recent development is the introduction, by SHAW and SHULMAN and their associates in Melbourne,[5–7] of bemegride ('Megimide') as a specific barbiturate antagonist 41 patients, 9 of whom were classed as "serious," were treated with this drug, and only 1 died[6] It is said that bemegride quickly brings the comatose patient to a "safe state" of light unconsciousness from which he recovers to full consciousness some hours later, presumably when the blood barbiturate level has fallen spontaneously (SHULMAN also uses amiphenazole ['Daptazole'], which is thought to reduce the toxicity of bemegride and to potentiate its action) But, though favourable results have been obtained by others[8–14] in small numbers of cases, the value of bemegride has not yet been fully assessed WRIGHT,[15] while agreeing that it has an analeptic action in poisoning by short acting barbiturates, believes that the specificity of a barbiturate antagonist should be proved in poisoning by long acting barbiturates Calculating the expected time of recovery of consciousness in 7 of SHULMAN's patients who took phenobarbitone, he argues that only 2 of them recovered earlier than they would have done if bemegride had not been given Here, and when he questions the safety of the "safe state," his argument is an indirect one, and further work is awaited on the relation between the blood barbiturate level and the degree of consciousness in patients treated with bemegride a preliminary report by HOLTEN[9] records that after administration of bemegride a patient became conscious despite quite a high blood-barbiturate level. Another finding of WRIGHT[3] was that in patients seen within four hours of taking barbiturates, gastric lavage produced appreciable quantities of the ingested drug, but that after four hours only negligible amounts were recovered BROUGHTON et al report that up to 4% of the ingested dose can be recovered by gastric lavage provided this is undertaken within twelve hours of ingestion But the doctor in the casualty room seldom knows what time has elapsed since the drug was taken and the prospect of recovering at least some of the poison from the stomach or œsophagus will encourage him to wash out the stomach without delay THOMSON and ALSTEAD[16] have lately described the technique they recommend

In 1954, HUNTER and GREENBERG[17] described 3 cases in which the symptoms were originally attributed to islet cell tumour of the pancreas but were later found to be due to chronic barbiturate intoxication This clinical impersonation led HUNTER and his colleagues to inquire into the effects of the barbiturates on carbohydrate metabolism, and we have lately published their findings[18] 16 patients who were receiving large doses of barbiturates daily were given two doses of glucose, and the levels of glucose and of pyruvate in the blood were followed Abnormally high levels of both glucose and pyruvate were found, but these levels, especially that of pyruvate, could be restored towards normal by giving vitamin B complex for two weeks before the test The abnormal electro encephalogram of chronic barbiturate poisoning was improved, and the symptoms of barbiturate withdrawal diminished, by giving vitamin B complex These observations recall the findings of GOULD,[19] who treated delirium, psychoses, and coma due to drugs (very often barbiturates) by giving intravenously glucose, aneurine (thiamine), nicotinamide, pyridoxine, and ascorbic acid The extension of this line of research into the biochemical changes produced by barbiturates may well lead to important developments in the treatment of both chronic and acute intoxication by barbiturates

New Kidneys for Old

THE report[20] of the successful transplanting of a human kidney by MERRILL and his colleagues of Harvard brings hope to those ill with progressive bilateral renal disease Earlier attempts at renal transplantation in man had not been successful[21–23] MERRILL et al have earlier reported their previous experiences in detail[24] In 9 patients with severe bilateral renal disease in whom kidneys were transplanted, permanent function was not maintained although in 1 patient—a doctor with chronic glomerulonephritis—adequate renal function persisted in the transplanted kidney for 5½ months

The knowledge that skin homografts between identical twins have survived permanently[25] and the recent report of a successful kidney transplant between dizygotic cattle twins[20] led the Boston workers to transplant a kidney from a healthy young man into his twin brother who had advanced and diffuse chronic glomerulonephritis Later, both diseased kidneys were removed The function of the transplanted kidney was excellent 12 months after the operation, and the patient has made a remarkable recovery Before the transplant he was very

Quarantine for Poliomyelitis

Replying to a question, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the Minister was advised that quarantine measures for poliomyelitis contacts, if they should be necessary, should depend on local and individual circumstances as assessed by the medical officer of health General advice was issued to all local authorities in July, 1954, and a form of notice suggested which might be addressed to contacts

Statistical Branch of Ministry of Health

Replying to a question, Mr R H TURTON, Minister of Health, said that a statistician was appointed in July, 1955, to advise on the collection, analysis, and interpretation of statistical information for the Ministry of Health The present staff of the statistical unit consisted of 15 executive and clerical staff and 6 trained machine operating staff

Medicine and the Law

Surgeon Cleared of Assault and Negligence

ON Dec 11, 1947, Miss A. H Baker performed an operation for hysterectomy on a patient, a doctor, then aged 43 The patient now sued Miss Baker for damages for alleged assault and negligence; among other things alleging that the operation had, and would continue to have, a bad effect upon her health, that it had been performed without her consent, and that it was totally unnecessary The patient gave evidence that although on entering the hospital she had signed a form of consent for the operation, agreeing to leave its nature and extent to the surgeon, she had thought that the operation to be performed was a curettage, and that anything that was done beyond that was done without her consent, she also alleged that, from the moment of her first examination, the surgeon had decided to perform a hysterectomy and had never communicated that decision to her Miss Baker's evidence was that she had specifically raised with the patient the question whether, if anything was found requiring hysterectomy, the patient would like her to continue at once while the patient was still under the anæsthetic, and that the patient had agreed Miss Baker said that when carrying out the curettage she found symptoms consistent with chronic fibrosis, and was able positively to diagnose that condition by the feel and sound of the curette, that she knew from her experience that the curetting would do no good in such a case, and that, having formed the view that the proper course was to remove the uterus, she performed the operation. Evidence was given that for upwards of three and a half years after December, 1947, the patient suffered from a severe mental and nervous disturbance, there was also evidence that, before the patient went into hospital, there had been matrimonial difficulties between her and her husband.

Mr JUSTICE BARRY said that the primary cause of the patient's breakdown was the domestic trouble but at a later stage it was substantially contributed to by worries in connection with the operation, primarily due to her fear of carcinoma which at that time she felt might have existed and which she feared had been kept from her knowledge, later that fear developed into anxiety as to whether the operation had been necessary There were two issues, the first—was the operation in fact performed with the patient's consent ?—resolved itself into a direct conflict of evidence and he had no hesitation whatsoever in accepting Miss Baker's evidence on this issue in preference to that of the patient As to the second issue—was the decision to perform the operation a negligent decision in that in making it the surgeon failed to exercise the proper care and attention which should be devoted by the surgeon to the consideration of a diagnostic problem during the course of an operation ?—he thought that the patient was quite wrong in thinking that Miss Baker had arrived at a firm decision to perform the hysterectomy before the curettage No surgeon with her experience would have done so as a result of a bimanual examination. The operation was unnecessary so far as carcinoma was concerned, and the case turned on whether he took the view that Miss Baker was telling the truth when she described her findings during the operation. He saw no reason to reject her evidence He was satisfied that she was justified in diagnosing fibrosis, and how could it be said that it was negligent to remove the uterus of a woman of 43 who was affected by fibrosis, even though it had not reached the advanced stage which would enable it to be detected by examination ? Miss Baker had had to reach her decision to perform a hysterectomy on clinical findings during the course of an operation, and he was satisfied that her decision was not only free from any taint of negligence but was a correct and proper decision to make The patient's complaint was without foundation.

On the question of costs his Lordship said that the litigation had to some extent been encouraged and complicated by the fact that wholly inaccurate documents compiled at the hospital, in particular the diagnosis and clinical abstract which were sent to the patient, showed the existence of a disease wholly different from that for which the operation was in fact performed. Miss Baker was in no way responsible for those notes, but she knew that they had been sent to the patient and her omission to point out to the patient that these were wholly inaccurate ought to be reflected in the order for costs, Miss Baker should, therefore, be awarded only four-fifths of the costs after the termination of the patient's legal-aid certificate Judgment was entered for the defendant with an order for costs accordingly

Every Man Expects England

A mother in her will, dated Oct 7, 1953, made no provision for her only son born in 1923, who was and always had been a mental defective In 1953 when the mother fell ill and was unable to continue looking after him, he was taken to a hospital in the National Health Service, where he was at the present time The mother, who died in December, 1953, left her estate of £2291 net to two friends The son's sole property was a sum of £750 The evidence of the doctor at the hospital where the son was a patient was that extra comforts such as games and gramophone records were beneficial to him, but that these now needed replacement By this application under the Inheritance (Family Provision) Act, 1938, the son (suing by his uncle as his next friend) asked that reasonable provision might be made for his maintenance out of the net estate of his mother.

Mr JUSTICE VAISEY, during the hearing, observed that some people expected the Welfare State to perform not only their financial obligations but also those of affection. Nelson's signal at Trafalgar should now be written "Every man expects England to do his duty."

Giving judgment, his Lordship said that in this case the mother had no doubt conceived the idea that the capital sum of £750 was adequate provision for the son, except in so far as he was maintained by the State The question was whether under the provisions of the Inheritance (Family Provision) Act, 1938, the son ought to receive some provision from the estate of the mother She had certainly not intended him to take anything from her estate, not from any lack of affection, but because he was being maintained by the State she thought that she was entitled to leave her property elsewhere

The son had some powers of enjoyment, such as the playing of games and of gramophone records, and there was no doubt that these extra comforts which the State did not provide were beneficial to him It was well-known that State hospitals were somewhat bare and lacking in the smaller pleasures of life such as could be provided with a little pocket money, and which a patient maintained by the State could have only from outside sources A testator was entitled to say that the State had assumed the burden of the parent, and a parent in making a will could, to that extent, assume that his parental duties would be carried out by the State There was nothing unparental or undutiful in that

The mother in her life-time had provided the son with the extra comforts, and his present application was that some grant should be made out of her estate so that he could continue to have those extra comforts indices, and standard deviations, to pause and think about Ethel Wise and her doctors They remind us of the reality among statistical shadows, of the humanity behind χ^2, and that Man is greater than his creations

Parliament

Purchasing Power of Incomes

Mr JOHN HALL asked the Chancellor of the Exchequer his estimate of the gross salary which, in 1938, would have given a married man with two children the same purchasing value, after tax, as he receives today from a gross salary of £2000 and £3000, respectively —Mr HENRY BROOKE replied About £633 and £859 respectively

Mr HALL Does the Minister think it right to impose additional taxation in the form of surtax on a purchasing value of £633 ?—Mr BROOKE My hon Friend is calling attention to the heavy burden of present-day taxation On that I could not agree with him more

Mr HALL asked the Chancellor what would be the gross earned incomes required today by a married man with two children to equal, after deduction of tax, the purchasing power of gross earned incomes in 1938 of £2000 and of £3000 per annum —Mr BROOKE replied About £12,200 and £34,600 respectively Mr HALL Is not this an apt illustration of the old saying that "The higher you go the fewer," and does not this act as a great discouragement to men and women who find that as they progress in their professions their standard of living falls ?—Mr BROOKE I think that what my hon Friend says is perfectly true

Mr HALL asked the Chancellor what salary he would need today to equal in purchasing power, after tax, the salary enjoyed by the holder of his office in 1938 Mr BROOKE replied About £75,000 Mr HALL Is my right hon Friend aware that I am almost overwhelmed by that figure ? May I ask him if he thinks that the holders of the august office of Chancellor of the Exchequer before 1938 were overpaid or alternatively, does he think that the duties and responsibilities of that office have lightened since 1938 ? If not, will he say when he proposes to take such measures as may be necessary to increase the salaries of the Chancellor and other Ministers and especially junior Ministers ? Is he aware that although it may be less difficult to become a junior minister than a bummaree, a bummaree is probably very much better off ?—Mr BROOKE I can scarcely answer all my hon Friend's questions, but I think that the original question has called attention to how hard it is, with present-day penal rates of taxation on large incomes, to remunerate adequately men in any walk of life who carry great responsibilities

In England Now

DURING the cold spell the only comfortable and contented creatures in the house have been the tropical fish in the surgery Thermostatically controlled at a steady 75°F, without a thought for the electricity bill, they watched us through their window on to the human world, passing and repassing with coils of electric cable, resuscitated oil lamps, and cans of paraffin, striving to keep ourselves and our environment unfrozen Indifferent to our difficulties two males out of the shoal of Rosy Barbs chose to don their mating dress, suffusing silver flanks with a blush of pink and edging their fins with borders of intense black They became quarrelsome, chasing one another through the water plants the other fish keeping judiciously out of their way The liveliest male lost none of his colour when he was netted and placed in a separate tank, and one of the plumper females was selected as his bride His display scored an instant success, for spawning began at once

It is regrettable that Barbs are bad parents, eating their own eggs or fry without compunction, so both fish were netted once again and returned to the shoal in the surgery The hatch was not a large one, but fry appeared from the thick of the plants in the next few days, thin threads of body behind two black eyes hanging under the surface film and darting an inch or so away if disturbed They are growing well now, fed on the fishy equivalent of 'National Dried,' a particulate suspension squeezed from a tube Apparently it is an acceptable substitute for the infusoria of the waters of India whence their forebears came

Letters to the Editor

REMUNERATION OF DOCTORS

SIR,—Following your publication last week of a letter from Dr Talbot Rogers and Sir Russell Brain on the subject of medical remuneration, I think it is desirable that your readers should be informed that at a very well attended meeting of the Royal College of Physicians of Edinburgh on Feb 7 the following motion was passed by an overwhelming majority

> "That the College, having received the report of a meeting between representatives of the General Medical Services Committee and the Joint Consultants' Committee, considers that no claim for a general increase in medical remuneration based upon 'the betterment factor' should be made at the present time, but believes that, if and when an appropriate time should arrive for such a claim to be made, the method of joint action proposed in the report is acceptable"

Royal College of Physicians
Edinburgh

STANLEY DAVIDSON
President

SIR,—I have been dismayed to read in the medical and lay press of the impending claim for increased remuneration for medical practitioners, and I hope you will allow me to state why I consider these claims to be ill timed and ill advised

It is stated that the object of the claim is to meet the decline in the value of money since 1950, or, in other words, to offset the effects of inflation I am fully conscious of the evils of inflation, but I believe the only effective counter measure is to do all one can to halt inflation At last the Government does appear to be making a serious attempt to grapple with this menace, but it seems highly probable that success will be achieved only if governmental action is supplemented by restraint and cooperation on the part of various sections of the community It is for this reason that I consider the present time to be particularly inappropriate for this claim Coming, as it does, from a big and reasonably prosperous professional group, which hitherto has been esteemed for its integrity, altruism, and intelligence, it will undoubtedly embarrass the present attempts to curb inflation, and if granted, will almost certainly contribute to further inflation and further taxation Obviously the granting of this claim would promptly be followed by similar claims from other groups in the Government services, the universities, nationalised industries, &c

This claim is to be deplored not only because it is contrary to the national interest, but also because it can result in no substantial benefit to the profession as a whole With the present structure of income tax it is obvious that against a background of continued inflation, as the gross income rises, increases in salary become of diminishing value in terms of both net income and purchasing power and thus can provide only a temporary relief, which would in the case of most doctors be small in degree and bear little relation to the increase in gross salary If the merry go round in inflation continues, the position of the higher salary groups must inexorably continue to deteriorate in relation to the rest of the community, despite repeated increases in salary

For these reasons I believe that, if the economic status of the medical profession is to be maintained or improved it is essential to do all that is possible to combat inflation and to resist, even if it entails apparent self sacrifice, any measure likely to encourage it If it is felt that more positive action is called for, I would suggest that, instead of pressing salary claims, consideration might be directed to the possibility of obtaining a modification of the present taxation system which would be more equitable to the professional classes It is some two years since the findings of the Millard Tucker Committee were published This report contained recommendations which would ease the financial position of many professional men, but I have heard no talk of its being implemented, nor of any interest in it being taken by those of our profession who claim to safeguard our economic welfare

University Department of Medicine,
Royal Infirmary Glasgow

L J DAVIS

CŒLIAC DISEASE

SIR,—Dr Véghelyi (Feb 4), commenting on Dr Sheldon's paper,[1] draws attention to his own work and that of others which showed that the pancreatic enzymes, particularly lipase may be inhibited by acute infectious fevers or gastro behind these memories of the past, the old road continues to its one contact with modern life, and it is the one thing of which modern life can justly boast—a country house that has been turned into the headquarters of the county library. So you must not think that the old road is a useless, stuffy, old fogey, for at its end it leads you into the world of books.

---

[1] Sheldon W *Lancet*, 1955 ii, 1097

* * *

It takes all sorts to make a laboratory as well as a world, as is shown by the delightful drawings in Professor Burch's book *Of Research People*.[1] The exhibitionist, the materialist measuring his bibliography with an inch-tape, the modest man, the cerebrator, the committeeman, and the research director are drawings fit to grace any laboratory bench. Unfortunately, perhaps, the text is more conventional. It is taken from a lecture on the problems confronting people in research today, and it gives, among other things, a serious account of the ideal research-worker, the ideal research director, and the ideal research assistant. It would be interesting to know if these ideal people exist in the flesh or if they are creatures of Professor Burch's imagination. Certainly it would be a thrilling experience to meet the ideal research-worker—a modest man, working peacefully in his garret, utterly absorbed in his own ideas, full of enthusiasm and zest, yet tempered with caution and deliberation. Professor Burch advises us to let him work alone, free from the responsibility of committees and teaching, free of all concerns about reports and research programmes. He might have added that our research-worker should be freed of all domestic chores. His clothes should be laid out for him in the mornings, his meals ready for him when he wants them, yet he should never be made to feel he must interrupt an important thought for food. He should do no gardening, no house-decorating or dish-washing, nor should he have to worry about the car, fuse-boxes, bills, holidays, income-tax, or shopping. On no account should his sleep be disturbed by crying children, and the advantages of a roughage-free diet seem worth exploring. If he does not produce lots of ideas under these conditions he should be wrapped in cotton-wool and sent to a conference abroad.

* * *

Fetching the coal from the basement the other evening, I was startled to find myself in the company of three attractive women in the altogether, two in the erect frontal position and the other reclining seductively on a discarded sofa. Far from being abashed they retained a distant haughty attitude, obviously socially indifferent to a mere menial. Lest my colleagues are tempted to volunteer for like duties, let me hasten to add that it was not a heavenly vision sent to reward the good deed.

Students, north of the Border, hold a Charities' Day each year. It started in the depressed 'twenties and has since become a highly organised procedure culminating in a fancy-dress procession second only to the Nice Carnival. The Eldest is having his first Charities Day and his crowd propose to convert a lorry into a pirate ship. A hunt round the female department stores produced the three young women temporarily housed in our basement before becoming the somewhat immodest captured maidens on the deck beneath the Jolly Roger.

As an anatomist I consider they have perhaps too much of the Grecian boy about the thighs and hips to promise fecundity, but that is a common feature of ladies of their profession—an unfortunate idealism perhaps, as the average mother of a family must find it difficult to squeeze herself into the clothes which fit so gracefully on the model. My wife's verdict was "It is like a basement in Paris." Again, let me hasten to add, an impression gained from lurid reading rather than factual knowledge.

One bad foot deserves another?—Brighton's "Happy Feet Week" is being held in the Corn Exchange.

Letters to the Editor

RESTRICTION OF ANTIBIOTICS ?

SIR,—I would like to compliment you on raising many important and topical matters in your leader (Jan. 28).

It is the duty of governments to safeguard the welfare of their subjects, and the New Zealand government has, I believe rightly, concluded that some control of antibiotics is necessary in order to protect the individual, even if it means restricting the doctor's freedom in prescribing the drug in question. There seems no danger of proper cases being denied the drug.

The unrestricted use of antibiotics, especially the wide-spectrum tetracyclines, has been shown to lead to two possible groups of harmful effects—toxic or sensitising reactions in the individual, and the development of resistant strains which will affect both the individual and the community as a whole. This state of affairs is believed to have arisen because of the excessive and unnecessary use of antibiotics in the past, and recent reports from hospitals quote figures suggesting that the majority of pathogenic staphylococci are now resistant to penicillin and to many of the other antibiotics. If this trend is allowed to go on then we shall soon reach the stage where these and other organisms are resistant to all of the known antibiotics, and then we shall have to rely on the ingenuity of the chemists to keep us supplied with an ever increasing number of new types to control these infections. The New Zealand government has therefore taken the bold step of restricting the use of one antibiotic, erythromycin, so that it is not abused and that it may be available for the treatment of infections which have proved resistant to other drugs.

After some ten years of the "antibiotic era" the time has surely come for us to reflect whether all these potent drugs are really necessary in the treatment of the many major and minor illnesses for which they are prescribed. The answer, in general practice at least, is undoubtedly that they are being used excessively. The vast majority of the common infections seen in practice will settle either on their own or with the aid of the relatively simple and safe penicillin and/or sulphonamides; the wide spectrum tetracyclines and chloramphenicol are only rarely necessary. This is appreciated by many practitioners. Thus in a recent study of acute chest infections in general practice in which eight practitioners took part it was found that in only 15% of cases were the tetracyclines used[1]; in a recent investigation, again on acute chest infections, organised by the College of General Practitioners and including some fifty-five practitioners from all over the country, it was found that in only 12% of cases were the tetracyclines or chloramphenicol used; and in my own practice over the past two years out of 722 cases of all forms of infection in which antibiotics were considered necessary these two types of antibiotic were administered in only 10%, all the others being satisfactorily controlled with penicillin or sulphonamides. These groups of general practitioners find, therefore, that tetracyclines and chloramphenicol are rarely needed in chest infections, which are probably the commonest group of infections in practice. It would be interesting to see similar figures from hospitals.

What of other infections in general practice? In my own practice I tried to assess the need for antibiotics in some common groups of infections. In series of 100 consecutive cases of each clinical group, penicillin or sulphonamides were found necessary in the following proportions: skin infections, 40%; acute bronchitis, 20%; pneumonia, 51%; acute tonsillitis, 32%; and acute otitis media, 32%. No complications were noted in those not given antibiotics. These are very small numbers, but they do suggest that we are tending to forget that in many cases the body's natural defences are quite adequate to deal with these common infections. It is also possible that, either because of or coincident with the introduction of the antibiotics, there has been a change in the nature of these diseases and that the causal organisms are not so virulent as in the past; this is probable in measles and scarlet fever, at least. Because of all these facts we should adopt more rigid criteria for the use of antibiotics both in general practice and in hospital. In the majority of cases where these drugs are considered necessary the safer penicillin, in adequate dosage, is usually

---

BILLROTH-I AND POLYA OPERATIONS

SIR,—In their paper (Feb. 4) comparing the results of these two operations Professor Goligher, Professor Moir, and Mr Wrigley report cases in which a recurrent ulcer appeared in the gastric stump after a Billroth I resection for an ulcer in the duodenum, and they speculate upon the cause of this unexpected complication.

Last year I showed,[1] from an analysis of 119 cases of associated gastric and duodenal ulcers, that such gastric ulcers usually develop after duodenal scarring has caused gastric retention. I reported that of 331 patients admitted to hospital with pyloric stenosis, 1 in 6 ultimately turned out to have a gastric ulcer as well, and I showed that gastric retention due to other causes might also lead to gastric ulceration. I quoted a prediction I had made in 1948 [2] that vagotomy alone, since it caused gastric retention, might well be followed by gastric ulcer. (Many instances have since been reported.) I also wrote of the Billroth-I gastrectomy: "I predict that its present widespread revival and popularity will lead to some recurrent *gastric* ulcers due to its use in cases where the creation of only small stomas has been possible."

May I join with Professor Goligher and his colleagues in urging restraint in the use of the Billroth I operation for patients with duodenal ulcer?

London, W.1. H. DAINTREE JOHNSON.

FACTORY IN A HOSPITAL

SIR,—Much as we may applaud Dr Baker's article last week as an attempt to improve the lot of the chronic psychotic, we accept his claims for its success only with considerable reserve and not a little scepticism. Those of us who have worked as institutional psychiatrists for, say, twenty years can remember other enthusiastic advocates of therapeutic procedures which have promised to empty, or half empty, our mental hospitals. With chagrin we recall, amongst others, the promise and relative failure of leptazol, deep insulin, leucotomy, and more recently acetylcholine and chlorpromazine.

The experiment at Banstead has lasted so far four months, during which time 3 patients have been discharged. On this evidence Dr Baker says: "It would not seem impossible in a hospital of this size, to discharge long stay patients at the rate of 100 a year, and this would mean that in twelve years the patient population of Banstead would be halved." By what arithmetical alchemy are these figures arrived at? Why not reduce to absurdity the estimated "emptying rate" and claim that in twenty-four years there would be no patients, no hospital, no factory!

We must point out, too, that rates of discharge and of cure are not identical. What follow-up studies has Dr Baker done on those patients discharged since the experiment began, and on those whose prior discharge, as he explains, made the room for the experiment available? What cognisance has he taken of the readmission-rate of patients discharged from Banstead into his own and other hospitals?

In all progressive mental hospitals—and it is obvious that Banstead must be included amongst them—there has been in recent years a change of policy and of heart in the handling of the chronic patient. "Total push"—that is, the attempt to keep all patients occupied on productive work or engaged in emotionally satisfying activities—has produced an enormous change in the atmosphere of the hospitals. Activity has usurped apathy; hope has replaced despair. As a practical consequence the superimposition of an "institutional psychosis" engendered by enforced idleness, which is the greatest insult to human dignity, on to the psychosis with which the patient was admitted is prevented. But, and this is the real heart of the matter, it is doubtful if this new policy has in any way altered the natural course and history of any of the so-called functional psychoses. Schizophrenia, for example, one of the greatest scourges of mankind, remains a chronic illness in which, despite all our efforts, remissions and relapses are to be expected.

In thus criticising Dr Baker's paper we have no wish to dampen his enthusiasm for his project. What we fervently hope is that he will not allow premature and extravagant claims to bring his good work into disrepute.

HENRY R. ROLLIN.
J. R. WATKIN.

Horton Hospital,
Epsom, Surrey.

Notes and News

After the year 1949-50 no supplementary estimate for the National Health Service was submitted until last year when the revised estimate called for a further £6 million. For the current financial year a supplementary estimate totalling £12,671,... net for England, Wales, and Scotland has been submitted. This will bring the total net cost of the service to £479,337,405 in the present year. Most of the additional money is required for the hospital service, for which the original estimate (£304,680,...) is increased by £8,729,000 to £313,409,000. In England and Wales, but not in Scotland, additional money is required for the pharmaceutical and general dental services—£2,043,000 for the pharmaceutical service (revised estimate £41,179,000) and £1,324,000 for the general dental service (revised estimate £28,069,000). (1955-56 Supplementary Estimate. Civil Estimates and Estimates for Revenue Departments. H.M. Stationery Office. Pp. 147. ...)

At the annual general meeting of the National Fund for Poliomyelitis Research on Feb. 8, a letter was read from Sir Harold Himsworth, secretary of the Medical Research Council, to Admiral Sir Charles Daniel, chairman of the Fund. Sir Harold said that in the view of the M.R.C., while vaccination with the present formalin-inactivated poliomyelitis vaccine should prove a most important advance, it would be unjustifiable to assume that the final answer to the problem had been found. Judging from early experience in the United States and elsewhere it was unlikely that the present vaccine would abolish poliomyelitis completely, although we might expect it to give a substantial measure of protection. It would be premature, therefore, to stop investigating alternative preventive measures, of which the most hopeful seemed to be vaccine made from living attenuated virus which would be given by mouth. Development of such a vaccine was still at an early stage, Sir Harold said, and would require further extensive fundamental studies of the properties of the virus.

On Jan. 25 the degree of M.S. of the University of London was awarded to A. R. Anscombe and P. A. Ring.

At a meeting of the council of the Royal College of Surgeons of England on Feb. 9, with Sir Harry Platt, the president, in the chair, an honorary fellowship was presented to Sir Walter Mercer, president of the Royal College of Surgeons of Edinburgh. The Hallett prize was awarded to T. N. Shanmugalingam (Ceylon) and Handcock prizes were awarded to J. G. Cruickshank (U.C.H. Medical School) and to P. J. Stiles (Guy's Hospital Medical School). Fellowships were granted in the Faculty of Anæsthetists to the following: Isabel B. Schooling, Sheila M. Parker, C. R. Jolly, A. H. Phillips, A. J. Merrifield, T. M. Young, A. J. Sims, R. I. Kerr, Patricia M. Lumb, Freda E. Prince White, R. P. Wise, J. L. Anderson, B. E. G. D. Bras, Thomas Thomson, M. G. Rolfe, Norman Laurie Smith, J. C. S. Ainley Walker, Daphne Burkinshaw, E. J. Delaney, Leon Kaufman, Merlin Marshall, Yee Kit Poon, D. G. R. Wright, B. J. Brandstater, R. J. Genever, O. H. French, A. C. Webster.

At a meeting of the Royal College of Physicians of Edinburgh held on Feb. 7, with Sir Stanley Davidson, the president, in the chair, the following were elected to the membership: G. L. Montgomery, A. Kennedy, J. H. F. Brotherston, K. K. Nayak, J. G. Cowley, H. A. S. Joseph, S. Zacharias, J. B. Barr, H. Khoh, M. J. Raymond, J. F. Hare, A. H. Kitchin, R. Pirrie, N. A. Shaikh, P. C. Sikand, A. L. Minhas, J. O'Neill, F. G. Roux, M. G. Williams, R. A. Main, M. L. Suri, D. Glaichen, I. B. Hales, M. Hallowell, P. F. Soysa, B. T. Dave, V. G. Wills, F. Chigier, J. F. Adams, J. T. Hughes, S. Sivasithamparam, S. L. Bhargava, S. Janardhana, R. A. W. Ratcliff, F. M. Narielvala.

At a meeting of the Royal College of Physicians of Ireland held on Feb. 3, with Dr F. J. O'Donnell, the president, in the chair, the following were admitted as licentiates and members: C. F. Brennan, John M. MacCarthy, N. J. O'Doherty.

A public conference on The Atomic Age—Perspectives and Problems is to be held on Saturday, March 10, at 2 P.M. at the Holborn Assembly Hall, John's Mews, London, W.C.1. Prof. J. B. S. Haldane, F.R.S., will speak on genetic effects of radioactive substances.

Dr Richard May has been appointed surgeon-apothecary to the household of Queen Elizabeth, the Queen Mother, at the Royal Lodge, Windsor.

Dr R. M. Hardisty, at present senior lecturer in clinical pathology, St. Thomas's Hospital Medical School, London, has been appointed senior lecturer (clinical pathologist) at the Welsh National School of Medicine.

The annual general meeting of the Mental Health Research Fund will be held at 1, Wimpole Street, London, W.1, on Tuesday, March 6, at 5.15 P.M. Sir Russell Brain, P.R.C.P., will give an address and Dr Arthur Hughes will show his film on the growth of nerve cells.

The National Institute for the Deaf has issued a new edition of its booklet containing an approved list of dealers in hearing aids. Copies may be had from the institute, 105, Gower Street, London, W.C.1.

Eighty nurses at a Manchester epileptic colony have decided to ban overtime work from March 1 (*Manchester Guardian*, Feb. 7). The nurses in four Lancashire mental hospitals have already imposed a similar ban as a protest against their pay and conditions of service.

At an extraordinary general meeting on Feb. 2 the National Association for the Prevention of Tuberculosis passed a special resolution to alter its constitution to enable its work to include all cases of the chest and heart. Proposing the resolution, Sir Robert Young, vice-chairman of council, said that the change was in line with current tendencies. Chest clinics nowadays dealt with many non-tuberculous conditions of the thorax and under the resolution voluntary help could in future be extended to such patients. The N.A.P.T.'s concern with tuberculosis would not diminish so long as there was need for it.

at they should take responsibility for this work for which lly qualified doctors are considered unsuitable Of the maining three technicians, one is a biochemical technician ho has little experience of blood grouping, and I am therefore ft with my hæmatological technician who does the day to day ouping and cross matching, and the senior technician As ese two live in the country and have neither transport nor lephones, and as the hospital has no transport of its own vailable at night, the only way these people could be obtained ould be by sending a taxi from the nearest town A delay f at least one hour would be inevitable before the grouping f the patient could even be begun, and several hours before he technician got home again, perhaps only to be wanted gain for an emergency in another department With only wo available technicians it is quite unreasonable to ask them o sacrifice their domestic arrangements to live in every econd or third week throughout the year

If the regional boards have taken note of the comments in our columns we may confidently expect either a considerable xpansion of existing pathological establishments, or instruc ions to send our emergencies elsewhere Meanwhile, we must eal with the situation by the best attainable, if not the most esirable means, with the limited staff allotted to us—and *this must, of necessity*, include residents performing emergency cross matching This difficult task is not made easier by the uncompromising statements attributed to Dr French and Dr Loutit, which can serve only as ammunition for use against the next victim of litigation

THE ÆTIOLOGY OF CLEFT VERTEBRAL ARCH IN SPONDYLOLISTHESIS

SIR,—Dr Mutch and Professor Walmsley are to be congratulated on their lucid description of the mode of ossification of the vertebral arch (Jan 14) This is highly relevant to the ætiology of separation from the rest of the vertebra of the inferior articular process, lamina, and spinous process This condition has a plethora of names—e g , pars interarticularis lesion, cleft arch (surely a misleading name ?), spondylo-schisis, and separation of the lamina—and is (as the authors say) only associated with spondylolisthesis (forward slipping of a vertebra) in about half the cases, whilst spondylolisthesis certainly occurs very frequently without any bony vertebral lesion There is therefore, only a loose association between the two conditions

But the authors should be criticised for their sweeping statement that "all critical observations have substantiated the view that a cleft in the pars interarticularis is the result of fracture of an ossified arch " This is by no means so, and the evidence for a purely traumatic cause is far from convincing For despite a century's research we are today unable honestly to answer the ætiological questions first asked by Killian [1]

Examination of fœtal and neonatal material by such careful workers as Mall,[2] Willis,[3] Batts,[4] and Rowe and Roche [5] has failed to bring to light examples of the anomaly in fœtal or neonatal material How then is it acquired later in life ? To say simply that it is a fracture begs the question

If the fracture (= the separation of the arch) is caused by trauma, what is the explanation of the widely differing ethnic and sex incidence ? How can this fracture be due to indirect trauma *and* be unilateral (as it sometimes is) ? Why is the thoracic region commonly affected in East Africans, the cervical region in Japanese and Eskimos, and the lumbar region in North American whites ? [6]

It is extremely difficult to answer these somewhat awkward questions The facts alone should make one wonder whether perhaps a genetic factor is not directly involved

It is a common fallacy to assume that a genetically determined defect is always congenital In fact the overt effect of genetic abnormality may only be revealed in late life Perhaps this may be the explanation of the present problem For Grüneberg (personal communication) has found a genetically controlled lesion in laboratory mice comparable to human spondyloschisis Willis [3] considered that structural failure at this point was facilitated by its penetration by large nutrient vessels In East African skeletal material the pars interarticularis of thoracic and lumbar vertebræ was pierced in about 10% of cases only with a nutrient foramen of variable size Possibly these nutrient blood-vessels are genetically determined phenotypes They are often absent, but if present, and large, may themselves cause the separation in childhood and adolescence or may so weaken the thin shell at the pars interarticularis that fracture follows trauma later on in life This would account for the rise of incidence with increasing age shown by Stewart [7]

DAVID ALLBROOK

TUBERCULOSIS STATISTICS

SIR,—Dr Baldry (Jan 28) raises an important point about the tuberculosis mortality rate If the number of deaths is obtained from the return to the Ministry of Health (T145) it should bear some relation to the figure given on the form T137 that is sent in by the medical officer of health, but these figures can never be the same In the case of T137 the public health authorities, certainly in this borough, enter persons as having died from pulmonary tuberculosis if those words are mentioned anywhere on the death certificate This is true whether or not the patient died from suicide, diabetes, or a cerebral catastrophe , but the official mortality-rate for pulmonary tuberculosis is calculated at the General Register office from the first part of the death certificates

If this absurd anomaly is to be corrected the whole problem of annual returns to the Ministry, regional hospital boards, and public health authorities must be considered afresh if only to prevent overlapping and unnecessary work This applies not only to pulmonary tuberculosis but to all medical, and especially clinical, statistics To what use do the Ministry put this information ? Is there any suggestion that their long term planning is in any way influenced by this information ? Is all the information ever published, not only in an accessible but also in an intelligible form ? (Some appears in the annual report of the chief medical officer of the Ministry of Health) Some regional hospital boards and some public-health authorities ask, either quarterly or annually for information that is almost identical to that supplied to the Ministry Do these bodies decide their future policy as the result of this information ? How do the returns from the mass miniature radiography units ,throughout the country relate to the information that is supplied to the Ministry from chest clinics, and especially to the notification rate ?

Reverting to the particular form T145, this is meant to reflect the work of the chest clinic but is badly designed Not only does the covering circular make extremely difficult reading but the questions asked on the form are obscure and local interpretation must vary considerably For example, in "Number of separate individuals (excluding transfers) examined during the year " the word " examined " means any patient examined by a medical officer *or who could have been deemed to have been so examined by virtue of the scrutiny of the radiographs* Consequently the total figures will of necessity be considerably higher in those clinics which run a chest service for general practitioners than in those where clinical examinations only are carried out

It is not possible to bring out in the returns that many contacts are examined by tuberculin testing only, others by radiography only, and a third group by clinical and radiographic examination and tuberculin testing There are other lacunæ in this form which make it almost worthless As a result the true over all state of tuberculosis in this country cannot be determined

I suspect that the Ministry working party on statistics has either been disbanded or has not met for some considerable time In any case a chest physician has never been a member The time has come to reconsider the whole problem of medical statistics as supplied to the Ministry of Health, and in particular the returns that are made from chest clinics These returns should include not only figures about tuberculosis but also information about chronic bronchitis, carcinoma of the lung and the many other important conditions that are now seen at chest clinics

Regarding the latter part of Dr Baldry's letter about notifications, one wonders how much uniformity is shown throughout the country—do all chest physicians notify primary hilar disease and cases of tuberculin conversion, or do they limit their interpretation of the term to overt clinical disease ?

Goldberger I have merely demonstrated a second way of illing the cat and in doing so have in no way repudiated the irst, and I think that most people who have surveyed all the acts that bear on the ætiology of lung cancer would be reluctant to admit that cigarette smoking alone subsumes them all

I strongly agree that smoking habits in New Zealand merit investigation, and I am well aware it is a defect in my thesis that this has not been done, but I have been unsuccessful in rousing interest in this though I have been trying hard for several years Perhaps the British Empire Cancer Campaign might support such an investigation, or the tobacco companies?

MEDIASTINAL SURGICAL EMPHYSEMA

SIR,—The curious complication of perforated duodenal ulcer described by Mr O'Donoghue (Jan 28) calls to mind a very similar case

The patient, a man aged 73, was admitted as an "acute abdomen" in March, 1954 He had been ill for two days with griping abdominal pain, abdominal distension, and occasional vomiting He was sent in with a diagnosis of large bowel obstruction There was nothing relevant in his previous history

The patient was obviously ill, with a grossly distended abdomen which was tender in all areas Extensive subcutaneous emphysema was present over the anterior and lateral aspects of both sides of the chest, this was more pronounced on the right side, where it extended up into the neck Radiography confirmed the presence of a pneumoperitoneum and of mediastinal and subcutaneous emphysema

The diagnosis presented certain difficulties Because of the patient's account of the onset of his trouble, and his subsequent progress, spontaneous rupture of the œsophagus seemed unlikely, in any event, this diagnosis would not explain the pneumoperitoneum No reasonable alternative explanation of the picture being forthcoming, laparotomy was undertaken A considerable amount of gas and gastric contents were present in the peritoneum A gastric ulcer was found on the posterior wall of the lesser curve at about its mid point This was adherent to the pancreas and had perforated at its inferior margin into the lesser sac The ulcer was freed from the pancreas and the perforation closed Examination of the abdominal œsophagus and cardia disclosed no obvious abnormality The peritoneal cavity was sucked out and the wound closed without drainage Convalescence was complicated by a burst wound which required re suture The patient has since remained in good health

As Mr O'Donoghue rightly points out, mediastinal emphysema is listed as a recognised complication of artificial pneumoperitoneum, but information on the subject appears to end there and I could find no published report on the mechanism by which this complication occurs Eventually I came to the conclusion that air must have entered the retroperitoneal plane at the site of the ulcer I believe that when leakage into the mediastinum occurs in artificial pneumoperitoneum, the air emerges from the peritoneum via the site of puncture and that spread occurs in the loose extraperitoneal layer to the under surface of the diaphragm The mediastinal tissues are then involved probably by way of the œsophageal opening

I find Mr O'Donoghue's suggestion that leakage took place as a result of rupture of the peritoneum of a hiatus hernia a little difficult to believe It would not have been applicable in my case, as no hiatus hernia was present In any event, we know from hernia at other sites how well the peritoneum stands up to stretching forces in the absence of injury Hiatal deficiency and herniation is very common, so also is peptic perforation

The inference is fairly clear The extreme rarity of mediastinal emphysema associated with peptic perforation must surely signify that its occurrence depends on the presence of some very rare circumstance or combination of circumstances Obviously a rare congenital peritoneal deficiency is a possible explanation, but I suggest that it is more likely to depend on some freak location of the site of the ulcer or some abnormality in the pathological progression of the lesion which allows access of air from the ulcer wall into the loose retroperitoneal plane In the vast majority of cases this is rendered impossible by obliteration of tissue planes in the vicinity of the ulcer as a result of inflammatory reaction

HOMOSEXUALITY

SIR,—May I explain to Dr Learoyd and Dr Howard, whose letters appeared last week, the purpose of sex codes ? They exist, firstly, to maintain the family as a social unit hence the prohibition of incest and adultery, and secondly, to balance the reproductive and non reproductive types of sexual activity with the population needs of the community Thus the ancient Greeks, who had to restrict the numbers of their ruling class to maintain their slave economy, encouraged a very moral type of pederasty, whilst the Hebrews, from whom our sex codes are derived, prohibited all non reproductive forms of activity, for they needed as large a population as possible to survive in competition with their warlike neighbours

Morality is and always will be the supremely important quality in any civilised community, but it is independent of any particular code Codes can and must change with changing conditions if a community is to survive in competitive circumstances

This principle is nicely illustrated by the history of the Lenten fast When this fast was established there was virtually no fresh meat in the country in the early months of the year, and it was important that such livestock as there was should be kept alive to fatten on the summer grass It was therefore advantageous that those who were not compelled by economic necessity should be encouraged to abstain from meat during Lent But *if the fast had* been continued by industrial workers once refrigeration had made supplies available all the year round, nutrition and output would have suffered relatively to non fasting groups Fortunately an excess of refined carbohydrates became available at the same time, so the principle of fasting was preserved by changing the code from meats to sweets without physiological harm

Our reproductive needs have changed so greatly in the last fifty years owing to reduced mortality at all ages that it is difficult to see how our society could have remained stable if Marie Stopes had not succeeded in her campaign for contraception Our code in respect of contraception is so far changed that a man who does not now control his reproductive capacity incurs no less censure than the man who did so only thirty years ago

Logically, those who are opposed to homosexual activity in the community should encourage homosexuals to persist in their activity For, as Professor Penrose pointed out to the B M A Committee, homosexuals represent one end of the scale of continuous variation of sexual polarity like height, and, if we wanted to reduce the number of tall men, surely we should welcome any activity that makes it less likely for them to reproduce themselves ?

Those who appreciate the contributions made by homosexuals in many walks of life might protest at the loss which this policy, if successful, would cause the community, but I feel it is just as immoral to enjoy the books, plays, or music of a homosexual, whom we should imprison if our policemen could trap him, as it would be to share in the profits of a fraudulent financier

Because the public hears very little of homosexual relationships other than those that pass through the police court, they think that all such relations are immoral But those who see cases, or anyone who cares to re read Havelock Ellis, will discover that most homosexuals have very high moral standards

London, N W 1 J F TUTHILL

ATHEROMA

SIR,—Dr Balme (Dec 24) asks whether hæmophiliacs ever got atheroma, should they live long enough, and also wonders if their aortas develop normally This was in reference to Dr Levene's interesting work with the electron microscope (Dec 10) The following case may partly answer the first question, but the evidence is highly suggestive only, since luckily this patient is alive and well and there is thus no microscopic confirmation

The patient, aged 67, has a family history of hæmophilia and himself has a classical and hæmatological picture of the disorder This man has lived a long and precarious existence, with multiple bleeding episodes—from circumcision, after tooth extractions, following many minor operations, into knee-joints, and finally from the urinary tract He is normotensive These severe bleeding episodes have become less frequent with advancing age I looked at the radiographs of his chest with a radiologist, and there was definite calcification may be first recognised The importance of a quick decision when the sex of a newborn child is in doubt needs no emphasis We recently reviewed[4] the value of the various techniques available From the point of view of treatment, the diagnosis of female pseudohermaphroditism (congenital adrenal hyperplasia) is urgent, for these girls may be salt losers and often have an addisonian crisis They are born with a phallus of varying size, but with fallopian tubes, uterus, and vagina The vagina commonly communicates with the urethra to form a urogenital sinus with an orifice at the base of the clitoris[5] Some types of intersex have identical external genitalia, and here cytological sexing—a positive chromatin test in patients with congenital adrenal hyperplasia—establishes the diagnosis, and this can be confirmed by an output of urinary 17 ketosteroids which is high for the patient's age Cortisone therapy must begin at once, and electrolyte abnormalities must be corrected Rare cases have been described in which the external genitalia have an identical conformation but in which, although the nuclear sex is also female, the output of 17 ketosteroids is normal and not raised as in adrenocortical hyperplasia These children should be brought up as girls, and may require plastic surgery later[6]

In girls with a webbed neck or coarctation of the aorta, cytological sexing and the finding of chromatin negative cells establishes the diagnosis of gonadal dysgenesis, allows a prognosis to be given about height and sexual development, and permits the important œstrogen therapy to be given at the age of puberty Gonadal dysgenesis is the extreme form of male pseudohermaphroditism, the patients are genetic males in whom complete feminisation has occurred (without mullerian-duct development—i e, fallopian tubes and uterus) Hypospadias may be regarded as the least extreme form of male pseudohermaphroditism, for here the urogenital sinus has not been quite converted to the normal male urethra Varieties of male pseudohermaphroditism between these two extremes may still pose problems in management and raise considerable difficulties for the plastic surgeon The general principle is that, both in male pseudohermaphroditism and in "true" hermaphroditism, the character of the external genitalia must still be a determining factor in the management of the patient If the plastic surgeon thinks it possible to construct a penis out of the phallus and if the cytological sexing is male, no problem arises If the external genitalia are so feminine that the plastic surgeon will be unable to construct a male organ and a penile urethra, then the child should be brought up as a female whatever the cytological sexing, and, if necessary, testes must later be removed and œstrogens given at adolescence These problems in male pseudohermaphrodites usually appear at puberty in "girls" who do not menstruate or who are developing external male characters Opinions differ, however, about their management, and sometimes no treatment can hope to achieve full success

We shall never remedy all the errors of sexual development we cannot bestow fertility where Nature has ordained barrenness, but we can ensure a normal gender rôle, a satisfactory sexual orientation, and the possibility of a happy married life for these patients These are great advances which until recently, have been won for us entirely by the chemists, the endocrinologists, and the plastic surgeons It is pleasant to record our indebtedness to a biologist, JOST,[8 9] who, by his brilliant experiments on rabbits, demonstrated that the rem of the foetal testis produced males with a feminine p development (the experimental equivalent of hu gonadal dysgenesis), while the castration of the fe foetus did not prevent differentiation in the female ge system, and to the cytologists, BARR and his associate who were the first to observe a sex difference in t nuclear chromatin of somatic cells

FRESH MILK OR TABLETS?

THE idea of giving schoolchildren a third of a pint of m a day for a halfpenny originated with the Milk Marke- Board, and, in 1934, the Board of Education recomme local education authorities to take advantage of the sch The Education Act of 1944 required local authorities to g milk to all children in maintained schools, and since 19 there has been no charge Until October, 1954, the sup was arranged and paid for by the Ministry of Food At th time regulations made by the Minister of Education placed local education authorities the responsibility of ordering a paying for the milk Local authorities were asked to introd normal tendering arrangements not later than April 1, 19 Fresh milk must be supplied other forms of milk cannot substituted without the approval of the Ministry of Educatio

Lately some remotely placed schools have been unable get fresh milk, and in a reply to a question in Parliament la October it was stated that seventeen education authori had, for this reason, been given approval to supply ch dried milk or milk tablets instead But the difficulty getting fresh milk to schools is not the only point at issue, a the question of cost has been causing concern to some counc The national bill for school milk is about £10 million a ye London pays about £750,000 and Surrey £270,000 per annu Both these county councils have discussed recently t reluctance of milk suppliers to allow discount, or to agre competitive tenders The Ministry of Education, in a let to local authorities on Dec 12, reaffirmed the policy that m for schools should be bought at competitive prices, and t Ministry gave assurance of Government support in pursua it Support is evidently necessary, for the recent report the Committee on Public Accounts shows that there is wid spread opposition from the milk trade to competitive tende ing "efforts to secure genuinely competitive prices h generally met with opposition by the trade even to the exte in some cases of denial of supplies to tenderers who offered discount" It seems that in the past year at least six lo authorities have been permitted by the Minister to use m tablets because the price asked for fresh milk was unreas able[11] Pending further decisions on policy, the Ministry advised local education authorities not to enter into long te contracts when they are unable to obtain reasonable suppl of milk at reasonable prices

The Minister of Education said in Parliament on Oct that although there was no suggestion that milk tablets w as good as liquid milk, they were an adequate substitu Fruit flavoured tablets have been produced (ten daily equivalent to a third of a pint of milk) and children are s to like them, especially children who have not previously fresh milk at school But in one area the children's react to the tablets was described rather cryptically as "by means unfavourable"

Many people will feel that there is little justification this country for substituting tablets for fresh milk except few country districts where there is no adequate supply pasteurised milk And certainly it seems very wrong to h to make the change because prices are kept up by suppl We are glad to note that in some places the introductio tablets has induced the milk suppliers to change their attitu and after further negotiations a lower price has been ag to But in many parts of the country the milk supp persist in their refusal to let local authorities have mil competitive price, and the Committee of Public Acco does well to speak severely of this unwillingness to coöpe in a service of such undoubted value to the children of country ere adhered to by all expectant mothers, the result would rtainly be drastic reductions in the numbers of maternal eaths, stillbirths, and neonatal deaths, in the number of xæmic patients occupying hospital beds, and in the number f babies filling the cots of premature baby units It ould save many lives, much expense, and much domestic pheaval, and obstetricians would be spared many grey airs

LEPTOSPIROSIS AMONG BRITISH TROOPS IN MALAYA

Sir,—Dr Fairburn and Dr Semple (Jan 7) suggest that enicillin and chloramphenicol play no useful part in the reatment of leptospirosis Having just returned from Malaya, where I was in charge of the medical wards in the third military hospital there at Kluang, Johore may I state briefly my opinions on treatment of this disease ?

In one year, during which time approximately two cases of leptospirosis a month were admitted, penicillin therapy in no case failed to give dramatic amelioration of symptoms and prompt (within forty-eight hours) reduction in pyrexia and other signs The dosage employed was 600,000 units four hourly for five days

I hope this letter may dissuade others from following the non antibiotic régime suggested by Dr Fairburn and Dr Semple

Dublin Lewis Clein

THE HOSPITAL STAPHYLOCOCCUS

Sir,—In your issue of Jan 7 Dr Brodie and his colleagues report finding that the carrier rate of staphylococci was doubled as a result of admission to hospital, and suggest that pseudomembranous enterocolitis in the first eight days after partial gastrectomy may be explained by the frequency of antibiotic resistant (serotype ac/–) staphylococci

That the hospital reservoir of staphylococci, rather than the strains carried by patients on admission, is in fact the main source of infection in staphylococcal enterocolitis is strongly suggested by evidence recently obtained at the Surgical University Clinic in Berne

In 10 out of 17 cases seen between June and December, 1955, a complete investigation was done, consisting of nose and throat swabs with tests for antibiotic sensitivity on admission, examination of the fæces at the onset of the disease, and (thanks to the kind assistance of Dr R E O Williams, of Colindale) bacteriophage typing The results showed that 2 cases were due to endogenous superinfection of the gastro intestinal tract from the nose with strains resistant to penicillin, streptomycin, and tetracyclines The remaining 8 cases were, however, caused by cross infection—in 7 cases with the same "house type" (phage combination 7/47/54/77, with minor deviations in some cases) This "house type" was encountered altogether 9 times over a period of four and a half months on three different wards 1 case was traced directly to a member of the nursing staff harbouring this strain in the nose We were fortunate enough not to lose any patients in this series 5 cases were treated with erythromycin, and 12 with the new antibiotic 'Rovamycin' ('Spiramycin')[1]

THE MUNDESLEY SANATORIUM A DISCLAIMER

Sir,—As Mark Twain said on a similar occasion, "Report of demise greatly exaggerated" Like all private sanatoria and most National Health Service sanatoria we have had to close whole blocks from lack of patients, and the prospects of survival as an establishment for the treatment of pulmonary tuberculosis are by *no means rosy*, but we have every intention of carrying on a bit longer

Mundesley was one of the first British private sanatoria to open 57 years ago, and we rather hoped to be among the last to close

Obituary

JOHN GEORGE FOSTER

O B E, B A, M B Dubl

Colonel Foster, who died on Jan 13 at the age of 83 in Queen Alexandra's Military Hospital, London, had served in the Royal Army Medical Corps for nearly forty years His retirement in 1937 he regarded only as an opportunity for service of a different kind, and as secretary of the Corps's charitable funds and as its historian he continued to work for it with devotion, kindliness, and scholarship

He was born in Athlone and graduated M B from Trinity College, Dublin, in 1896 Four years later he joined the R A M C During the South African war he saw active service in Cape Colony, Orange River Colony, and the Transvaal In the first world war he served in Mesopotamia till 1920 He was three times mentioned in despatches and received the brevet rank of lieut-colonel He was appointed O B E in 1919

In 1929 he took over the secretaryship of the R A M C Benevolent Society and the R A M C Fund, and he continued this work throughout the second world war, visiting his office daily whatever the state of the blitz might be An operation for the removal of an eye in 1944 he allowed to be only a temporary handicap "It causes errors in typing," he wrote, "but I hope I shall surmount this very quickly"

As a historian he was responsible for part of the roll of the Army Medical Services which goes back to 1666 Foster's Roll, which covers the years from 1898 to 1933, will be a fitting memorial to its compiler From the records which he had gathered for this work and from his own wide knowledge of the Corps, he had for many years helped us in preparing obituaries of serving officers He was also an authority on military medals and decorations, and he had lately given his own fine collection to the R A M C historical museum

A colleague writes "By the death of Colonel Foster all ranks of the R A M C have lost a real friend For the 20 years he was secretary of the R A M C Benevolent Society and the R A M C Fund, I was closely associated with him on their committees and I would like to record what a devoted secretary he was and how deeply interested in his work He would spare no trouble in seeking information which might enable officers, other ranks, or their families who were found to be in distress or in need to receive such help as could be granted to them Each case became his personal interest He possessed in a remarkable degree the faculty of detecting an applicant for help whose case was not genuine How great a friend he was to the R A M C may not, I fear, be fully realised, because he was a quiet and unassuming man very kindly and considerate, who shunned the limelight and worked unobtrusively He showed his interest in the Army generally by his knowledge of its history, which he implemented by a magnificent collection of British war medals"

A Scandinavian correspondent informs us of the death last month in Sweden of Dr Ivan Bratt, well known for his system of alcohol control known as Bratt's system Soon after qualifying in medicine at the age of 25 he threw himself into the discussions raging over the abuse of alcohol in Sweden His system of alcohol control hinged on the right of every individual to a certain amount of alcohol, but only so much and no more for each Sweden has only recently abandoned this system in favour of greater freedom of alcohol consumption Bratt also made his mark as director of Svenska Kullager Fabriken and in this post he showed great administrative ability He retired during the war, and he spent his last years on his estate in Södermanland, Sweden His life was saddened in 1940 by the death of his wife in a German air attack outside Paris, during which he himself was also wounded by a bomb splinter He was 77 years of age

Births, Marriages, and Deaths

BIRTHS

Dickinson—On Feb 6, at University College Hospital, London to Elizabeth, wife of Dr C J Dickinson, son—Mark John widely held and best substantiated view, however, is that the cavernous transformation is entirely secondary to a slowly developing occlusion due in most cases to thrombosis The remarkable extent of the compensatory changes is, according to Gibson and Richards,[8] due to local conditions around the portal vein, especially the relatively high venous pressure and the close anatomical relationship between the accessory portal veins and the main stem It is these factors that favour the formation of cavernous tissue around the portal stem, since all the compensatory collateral vessels are bunched together with the main vein in the hepatoduodenal ligament Usually there is little evidence of the underlying cause of the thrombosis Predisposing conditions such as syphilis or blood disorders (e g , polycythæmia) have proved to be unimportant The most probable cause is some low-grade intra abdominal infection leading to a chronic pylephlebitis

Treatment must obviously be directed towards the relief of the hypertension in the portal system The involvement of the portal vein and usually the splenic vein may make a short circuit operation difficult or even impossible In such cases direct treatment of the œsophageal varices may become a necessary life saving measure

A HYPOGLYCÆMIC PUZZLE

SEVERE spontaneous hypoglycæmia is uncommon, and of several possible causes,[1] islet cell tumour of the pancreas and liver disease are probably the best recognised A more unusual cause is a large upper abdominal tumour not arising from the pancreas and not associated with extensive destruction of the liver, and such a case has recently been described by Silvis and Simon [2] The presenting features were personality changes and weakness and faintness in the morning Later the patient had two episodes of hypoglycæmic coma in which his blood-sugar levels fell to 35 and 32 mg per 100 ml Consciousness was promptly restored by intravenous glucose A large hard mass was felt in the right flank, and he was accordingly prepared for operation by the administration of 400 g of glucose daily for four days A huge ovoid retroperitoneal tumour was found, occupying the entire right posterior part of the abdomen and involving the iliopsoas muscle The tumour extended posteriorly between the transverse processes of the upper lumbar vertebræ, and this part had to be removed at a later operation The specimen weighed 1200 g and proved to be a retroperitoneal fibroma Immediately after operation the glucose requirements and the glucose-tolerance test became normal Eighteen months later there was no evidence of a recurrence and there had been no hypoglycæmic attacks or other symptoms

Silvis and Simon draw attention to 5 previously reported cases in which hypoglycæmia was associated with large tumours not arising from the pancreas In Seckel's case,[3] hypoglycæmic coma was associated with a massive fibroma above the right lobe of the liver, bulging against the medial aspect of the right leaf of the diaphragm The pancreas was normal and no metastases were found An assay of the fibroma for insulin was negative The patients of Hines [4] and of Arkless [5] had sarcomas in the upper part of the abdomen and suffered from hypoglycæmic attacks, in both the pancreas was normal Rosenfeld's 2 patients[6] had peritoneal pseudomyxomatous cysts

No one has produced a convincing reason why these patients had hypoglycæmia The pathology of the tumours varied In the one assay reported no insulin was detected, and from the histology of the other tumours it seems improbable that they produced any internal secretion with a hypoglycæmic action Hepatic failure could not be blamed Excessive utilisation of glucose by the tumour is unlikely since extensive carcinomatosis and large benign growths generally lead to a rise rather than a fall in blood sugar [7] The common features of the reported cases are large tumours pressing on structures in the upper and posterior part of the abdomen and displacing viscera The riddle remains to be solved

Letters to the Editor

Anticonvulsant Action of Acetazolamide—After reading your annotation (Feb 11) we feel that it is a matter of duty to describe some results of a research on the biochemistry of epilepsy in progress at the Burden Neurological Institute In view of the trend of your annotation, it appears to be a matter of some urgency to point out the great therapeutic efficiency of acetazolamide in inhibiting petit mal attacks

In assessing any drug in the treatment of epilepsy the usual rule is to add the drug to the treatment that the patient has been receiving for some considerable period Without, therefore, varying the treatment that had obtained for a minimum of three months, 70 such cases of petit mal were given in addition a daily dose of 250 mg of acetazolamide (Diamox kindly supplied in ample quantity by Messrs Lederle) 51 of these cases were attending the Burden Neurological Institute clinic, and to these were subsequently added 19 similar drug resistant cases attending the Musgrove Park Hospital, Taunton It must be emphasised that only patients with daily minor attacks were selected The patients were mostly children and adults aged 6–35, and the fit incidence varied from about a hundred attacks to one attack a day, and all cases had resisted attempts to abolish the daily incidence of attacks with every form of drug treatment No case with a daily incidence of less than one attack was considered Of all 70 cases, only 2 were recorded as having shown no improvement at all 25 patients had no further attacks during the first month of treatment with acetazolamide In the remaining 43 cases the attack incidence dropped to one or two during the month During the second month of treatment the improvement was maintained and the number of those still having occasional petit mal attacks diminished to about 20 In the third month some of the cases which had responded by total absence of attacks had one or two further attacks, and in 1 case, where before treatment the daily incidence had been almost uncountable (probably more than 200), the incidence after being inhibited completely for the first two months reverted to two or three a day In such cases increasing the dose to 500 mg per diem led to some further improvement Most convincing were the effects of suspending the treatment Even twenty four hour abstention generally resulted in reversion to the pre condition

At this stage we prefer to make no assessment of the effect on major attacks, and it is only the feeling that we are not justified in withholding information any further as to the phenomenal effect of acetazolamide on cases of resistant petit mal attacks that has led us to ask you to publish this letter No side effects, beyond somnolence and occasional formication of the extremities in a couple of cases, were noted—
Prof F GOLLA, F R C P, R SESSIONS HODGE, M R C S
(Burden Neurological Institute, Bristol)

Billroth-1 and Polya Operations—The high incidence of re ulceration after a Billroth I partial gastrectomy in the treatment of duodenal ulcers, demonstrated by the Leeds professorial unit (Feb 4, p 220), is of great importance at this time when the popularity of the operation is increasing In the majority of cases the recurrent ulcer was in the stomach This gastric ulceration is possibly comparable to that after simple vagotomy for duodenal ulcers (L R Dragstedt, H A Oberhelman jun, O S Evans, S P Rigler, *Ann Surg* 1954, 140, 396) which is apparently produced by gastric stasis due to the reduced gastric tone and incoordinated peristalsis since it does not occur if the stomach is adequately drained by a gastroenterostomy If the gastric recurrences after gastrectomy are also due to stasis, vagotomy would be expected to increase stasis and worsen the condition—as appears to have happened in a third of the cases so treated

The cause of gastric ulceration after operations for duodenal ulcers, in which gastric stasis has been produced, is unknown but Dragstedt has demonstrated experimentally a possible explanation In dogs with a denervated Pavlov pouch artificially produced pyloric stenosis increases the rate of gastric secretion and may produce a gastric ulcer, if the stasis is relieved by a gastro enterostomy, there is no increase in secretion and ulceration does not occur Similarly vagotomy by decreasing the tone and peristalsis, causes gastric stasis and produces an increased flow of gastric secretion from the denervated gastric pouch

While conclusions drawn from experimental findings are sometimes invalid for man, the similarity of the results here roved treatment by clearing secondary infection but no g is known to be specific against the trachoma virus, which never been satisfactorily isolated, and which does not vive the journey to laboratories in other countries The r laboratory will be the first built in a trachomatous area l its position is medically ideal because most of the 400,000 ugees in Jordan have trachoma

The Order of St John has maintained a hospital in Jeru- em since the 7th century, the present hospital was ended by no less than 183 000 outpatients last year, but it too small, and land has been bought and building plans are advanced for a new 75 bed hospital, which will take part the trachoma investigation The research will be sponsored d guided by the Medical Research Council, and the research am will work in association with the virus laboratories of the ster Institute and the Institute of Ophthalmology in London nancial support has been received from the British and iddle East governments, the World Health Organisation, cal oil companies, and the Wellcome Trustees, and with its wn contribution of £290,000, the Order has sufficient funds o launch the research scheme and maintain it for seven years

APPROVED NAMES FOR DRUGS

The British Pharmacopœia Commission has issued the ollowing new supplementary list of approved names

pproved name	*Other names*
usulphan	1 4-Dimethanesulphonyloxybutane Myleran
uthalitone Sodium	A mixture of 100 parts by weight of the mono sodium derivative of 5-allyl 5-*iso*butyl-2 thiobarbituric acid and 6 parts by weight of exsiccated sodium carbonate Transithal
Diacetylnalorphine	Diacetyl N allylnormorphine
Halopyramine	N *p*-Chlorobenzyl-N N dimethyl-N-2 pyridylethylenediamine Synopen is the hydrochloride
Nicoumalone	3 (2 Acetyl 1 *p* nitrophenylethyl)-4 hydroxy coumarin Sinthrome
Probenecid	*p* (Di *n* propylsulphamoyl) benzoic acid Benemid
Promethoestrol	3 4-Di (4 hydroxy 3 methylphenyl) hexane
Propylhexedrine	1-*cyclo*Hexyl 2-methylaminopropane Benzedrex
Trimetaphan	4 6-Dibenzyl 5-oxo 1 thia 4 6 diazatricyclo [6 3 0 $0^{3\,7}$] undecanium Arfonad is the (—)-camphorsulphonate
Verazide	1-*iso*Nicotinoyl 2 veratrylidenehydrazine

On Saturday, Feb 18, at 11 A M at the London School of Hygiene and Tropical Medicine, Keppel Street W C 1 this society will hold a symposium on the structure of nucleic acids and their rôle in protein synthesis

Royal Statistical Society

On Tuesday Feb 28 at 5 30 P M the medical section of this society will hold a meeting at the Westminster Medical School, Horseferry Road, London S W 1 when Mr F Le Gros Clark will speak on Ageing in Industry

Course on Chronic Rheumatic Diseases

A course on this subject will be held at the rheumatism unit of St Stephen s Hospital Fulham Road, London, S W 10, on Saturday and Sunday, March 17 and 18 1956 The opening speaker will be Prof D V Davies whose subject will be the Capsule and Synovial Membrane of Joints The following will also speak Dr Francis Bach, Dr Grace Batten Dr Raymond Daley, Dr Philip Ellman Mr H. E Harding, Dr F Dudley Hart, Dr J A Purser, Dr P D Samman, Dr Gordon Signy Further particulars can be had from the secretary, Fellowship of Postgraduate Medicine, 60 Portland Place, W 1

British Tuberculosis Association

This association is to hold a joint meeting with the Irish Tuberculosis Society in Dublin on May 4 and 5 The programme will include papers on primary tuberculosis in adults the relation between cardiovascular and chronic lung diseases, and the M R C chemotherapeutic trials Further particulars may be had from the administrative secretary of the association, 59, Portland Place, London, W 1

British Diabetic Association

The annual Banting meeting of this association will be held on July 6 and 7 at King s College Hospital, Denmark Hill, London, S E 5 This year it will consist of a postgraduate course for doctors in charge of diabetic clinics, registrars and others Early application should be made to the Association at 152, Harley Street, London, W 1

Arthur Hall Memorial Lecture

In memory of the late Sir Arthur Hall the Sheffield Medico Chirurgical Society and other bodies in Sheffield have endowed a triennial memorial lecture The first lecture is to be delivered by Sir Francis Walshe, F R.S, on Thursday March 22, at 8 P M at the University of Sheffield His subject will be Medicine in the Framework of the University Applications for tickets should be made to the registrar of the university Sheffield 10, before March 10

National Association for Maternal and Child Welfare

The annual conference of this association will be held at Cardiff from June 20 to 21 The theme of the meeting will be Safeguarding the Family, and the speakers will include Prof Dugald Baird, Prof Wilfrid Gaisford, Prof A G Watkins, Dr Elenora Simpson, Dr Harold Cohen, and Dr J Stevenson Logan Further particulars may be had from the secretary of the association, Tavistock House North, Tavistock Square London W C 1

Nutrition Society

On Saturday, March 10, at the London Medical College Turner Street, E 1, this society will hold a symposium on Diet and Anæmia The chair will be taken by Sir Stanley Davidson and the speakers will include Dr P B B Gatenby Dr G R Wadsworth, Prof B S Platt, and Prof A W Woodruff Further particulars may be had from the hon programmes secretary of the society, Dr R J L Allen c o Beecham Foods Limited, Brentford, Middlesex

Laboratory Animals Bureau

The ninth congress of this bureau will be held at the Royal Veterinary College, London, on Wednesday and Thursday, April 11 and 12 On Friday, April 13, there will be a symposium, under the chairmanship of Prof J W Howie, on infections in laboratory animals Further particulars may be had from the bureau, Medical Research Council Laboratories, Holly Hill, London, N W 3

Diencephalic Control of Endocrine Activity

The Milan section of the Italian Society of Experimental Biology is to hold an international symposium on this subject from May 3 to 5 under the presidency of Prof W R Hess and Prof Emilio Trabucchi Further particulars may be had from Dr S B Curri and Dr L Martini, c/o, Instituto Farmacologia, Universita di Milano Via Andrea del Sarto, 21, Milan.

Compulsory Nursing ?

The difficulties of many hospitals in recruiting nurses were discussed last month at a meeting of the Wakefield A Group Hospital Management Committee (*Yorkshire Post*, Jan 26, 1956) Mr Lawrence Richmond the chairman, said that the position was so grave that it should be dealt with at a national level He was tempted to ask whether the time might not come when compulsory service might have to be contemplated, under which young women could be directed to nursing in a category equivalent to a State-enrolled assistant nurse Dr Moray Melvin, the vice-chairman said that one small measure after another had been tried but they had never got down to anything really effective ' At the back of my mind I have felt that we may be driven to compulsion " After discussion the committee decided to ask the Ministry of Health to take immediate steps to examine salary grades and conditions of service, to ascertain whether they are such as to attract young women to nursing way to hospital on the day he was first sent there, and the cause of the death was described as extensive pulmonary tuberculosis *which would have been discovered if he had been X rayed* Surely, physical signs and symptoms have not disappeared to the extent that only at death is it possible to see that the patient was not healthy ?

Mass radiography must not claim the discoveries made by practitioners An increasing discovery of active pulmonary tuberculosis *by mass radiography* would indicate a progressive degeneration of clinical medicine In fact I regard the propaganda associated with such "medicine" as mass radiography as *the* iridescence of decay —JAMES F BRAILSFORD, F R C P (Birmingham)

Homosexuality —Dr Tuthill's reasoning (Feb 11) is throughout based on expediency and not morality People are inclined to call "right" that which is common or necessitous behaviour Right behaviour is based on personal judgment in given circumstances, and depends solely on the dictates of conscience Common practice has never really been the yardstick of moral behaviour, *much as some moralists would have us accept this* Numbers do not sanctify Dr Tuthill's "logical" inference—that encouraging homosexuality ensures a limiting of their numbers—depends *on an analogical argument*, which is dangerous, and on the implication that homosexuals beget homosexuals, which is a non sequitur Homosexuals may well have "high moral standards", but this part, Sir, by no means presupposes the whole —D O HANCOCK, M B (Manchester Royal Infirmary)

Tuberculosis and Liver Biopsy—You have drawn attention (Dec 31) to work on liver biopsy in tuberculous patients You regard the finding of tuberculous lesions in the liver in a *fair number of these cases as of considerable importance from* various points of view Most of the patients had no clinical signs of generalised tuberculosis

Tuberculous lesions and tubercle bacilli have previously been demonstrated in bone marrow obtained by aspiration from patients with miliary tuberculosis (E M Schleicher *Amer Rev Tuberc* 1946, 53, 115) In acute hæmatogenous tuberculosis other workers (S Katz, S Lifschutz *Med Clin N Amer* 1950, 34, 1817) have cultivated tubercle bacilli from the bone-marrow in 67 out of 75 patients They believed that the method was of diagnostic value

However, the simpler and safer procedure of bone marrow aspiration seems to be worth considering also in less fulminating cases of tuberculosis It might be as informative as liver biopsy —LARS ENGSTEDT, M D (Department of Medicine, Karolinska sjukhuset, Stockholm, Sweden)

Electro-encephalography in Children with Recurrent Abdominal Pain —The painstaking investigation reported by Dr Apley and his colleagues (Feb 11) demands careful analysis The groups of children described are not quite comparable Of the 133 who had abdominal pain 96 came for investigation as outpatients, while 37 were picked up at routine school medical inspections For the 133 with no such pain the corresponding figures were 55 and 78 Though it is not stated in the paper, the outpatient children were drawn from far and wide, and include children of all social classes and all grades of mentality In the countryside of the West of England children drink much raw milk Tuberculous mesenteric adenitis and brucellosis, which may cause recurrent abdominal pain, are still extant here The outpatient group may be unduly loaded with such cases The school group, however, came from schools in Bristol (where only safe milk is drunk) It is not stated how many they were or of what type I suspect that special schools for the educationally subnormal and physically handicapped were not included Certainly the children of richer parents and those who go to boarding or private grammar schools have not been included Attending school medical inspections armed with a questionnaire is of doubtful value Dr Apley and I have done this together in the past I have pointed out before that the parents of "normal" children at such inspections are very loth to admit any abnormality in their children (*Dent Rec* 1953, 73, 519) When they come to hospital a different story may be obtained I understand that different persons interviewed the parents in the outpatient department and at the schools

What is more important is that patients who had fits have been excluded from both groups I have tried to show that an important factor in the diagnosis of masked epilepsy is a history of fits, or fits occurring later in the disease (*Brit med J* Jan 28, 1956, p 233)

Finally these workers ignore abnormalities shown by the response of the electro encephalogram to hyperpnœa and photic stimulation If these are included 18 of the 133 children with pain had abnormal electro encephalograms while of the 133 without pain only 13 had abnormalities —HUGH WALL M R C P (Bath)

In England Now

"ALL change here for the North Pole" our genial bus conductor called as the bus stopped at Euston, his only outward concession to the weather a woollen scarf His muffled apathetic passengers, clumsy in their clumping boots, smiled wanly but politely "Cold enough here" one of us murmured in a gallant attempt at the response which is the London bus conductor's due "That's where you're wrong" he said, 'it's colder here One degree warmer here than it was in the Arctic Circle yesterday " Congenital hibernators to a man, we gazed at him with admiration Master of his bus and his fate, by our standards lightly clad, abreast with the latest—most stimulating, if not most accurate—weather reports, he refused to lower his professional standards On his bus passengers should still be offered tickets, encouragement, and the news of the day

Obituary

Dr W L H DUCKWORTH

Dr Duckworth, the Cambridge anatomist and anthropologist, has died at the age of 85

Looking back over the years (writes Sir Lionel Whitby) it is simple to give a general appreciation of the influence of "Ducker" on the Cambridge Medical School, but it is more difficult to describe this subtle influence in appropriate words His brilliance as a teacher was outstanding, for he could clothe *the dry bones of anatomy* with living and vivid fact beautifully illustrated with a few deft strokes on the blackboard in coloured chalk But perhaps his greatest impress *was on the student as an individual, and thousands* of them in his time must have passed through his sensitive hands—which had the long and restless fingers of the accomplished artist

During the more than sixty years that he served the Medical School as demonstrator, lecturer, and reader, it was Duckworth who captured the admiration, the devotion, and the sincere *affection of all medical students* who *came to* Cambridge And this, irrespective of class, college, creed, colour, or whether they were just nice men (or women), or ordinary men, or *lazy* men, or energetic men, or *great athletes*, or clever men who took a first in part I of the natural sciences and another first in part II devoted to the vagaries of embryology, morphology, and comparative anatomy in which Duckworth had an international reputation The laggard loved him (he was kind in a viva though he would not tolerate ignorance), the women adored him (not only was he tall and lithe and handsome but also he was always the natural courtly and courteous gentleman who never bullied, and they respected him because he never allowed feminine charm to take the place of factual knowledge when his signature was required), the average student was happy, indeed flattered, that *Ducker* always knew his name, and he could *straighten* a chaotic dissection in a few seconds with his familiar "and here, or hereabouts, we hope to find, in fact we do find "

Duckworth was happy in his work, his play, *his* college, and his innumerable friendships He never murmured nor wavered for a moment in his loyalties, when he was not elected to the chair of anatomy, to which the *whole student* population over many years would have hailed him with unanimous acclamation At a difficult period of the last war he was chosen to be Master of his college, Jesus College , *and in* his declining years, well into the 80s, the wheel turned full circle, for he became a demonstrator again as well as an occasional lecturer *to the delight* and profit *of many young enough* to be his great grandchildren , they were fortunate to be taught by a master and to share the privilege and rich experience which so many Cambridge men *have* treasured all *their* lives

He suffered a great *sorrow* with the death of his wife on *St* Valentine's day in 1955 He himself joined her exactly one *year afterwards*

Dr C J WILSON, C M G , has died in East Africa at the age of 76

Printing of The Lancet

The difficulties that we mentioned a fortnight ago have now come to a head, and issues of The Lancet are likely to be in token form until normal work is resumed in the London printing-houses We can only express our regret that for the time being, we are prevented from fulfilling properly our obligations to subscribers, contributors, and advertisers

Violence

Violence, whether elemental or human is always news But reports, and even investigations, of its effects seldom reveal its cause In the past month two such reports have come from mental-deficiency institutions in Scotland in one[1] some nurses were tried and acquitted on charges of ill treating patients, and in the other[2] there was an apparently spontaneous outbreak of violence by a group of patients Happenings of this kind are, of course, more likely in institutions—ranging from prisons to mental hospitals—where groups of people are detained against their will, and the basic causes are no doubt always much the same Just as the force of an explosive charge depends on its chemical instability and the degree of compression to which it is subjected, so also do instability and constraint determine the violence of human reactions It is largely because they are unstable that mentally sick persons come for treatment and mental defectives have to be placed under care unsoundness of mind and a deficiency in mother wit are not in themselves grounds for medical or legal action Hence, all mental hospitals contain potentially explosive material and one certainly cannot expect minor individual outbursts to be less common in them than in the community outside But they will not act as detonators for a major explosion unless the main charge has been unduly constrained

There are two historical reasons for the constraint of the mentally sick (who of all people, are least able to tolerate it) first, the public demand for protection from something fearful and unintelligible, and secondly the belief that self discipline could be instilled by force Modern "open door" methods of treatment have done a great deal to reduce tension and the chances of violence, but where they have been most successful they have consisted in much more than the unlocking of doors Freedom to do nothing is not worth having, but so many patients have been inactive for most of their lives that to fit them for a measure of liberty is really hard work, of which the nurses bear the brunt The custodial attitude of the mental attendant is deeply rooted and to alter it requires both imagination and courage In its early stages so radical a change imposes considerable strain on the nurses, and these, feeling insecure, may be tempted to deal with the inevitable setbacks by resuming restrictive and even punitive measures But there is ample evidence that, once this stage is passed, the new liberty to be occupied, backed by the means to live a more active life, relieves the very ills for which restraint was imposed

In the prevention of violence much attention is still paid to the classification of mental patients, because it is manifestly unwise to store the detonators with the charge, but this reasoning loses much of its force if the charge is dispersed In fact there is evidence that an unstable patient is less likely to cause trouble if he is admitted to a well-behaved group than if he is forced to associate with his own kind Modern treatment aims to build up self-respect and self discipline from within The diminution in outbursts of violence among patients, and in allegations of ill treatment against nurses, are true measures of its success

Barbiturate Poisoning

In one of our recent issues[1] Miss Eileen Brooke gave some figures about deaths from barbiturate poisoning in England and Wales in the years 1939–54 In 1954 391 people committed suicide by taking an overdose of barbiturates—eight times as many as in 1945 As there was no corresponding rise in the total number of suicides during these years, it is clear that barbiturates are increasingly preferred as a means of self-destruction One obvious reason for this is the ease with which the mentally ill can obtain them in lethal amounts About 1 in 12 of all National Health Service prescriptions are for drugs containing barbiturates and as we have said before[2] there are considerable risks in repeatedly handing out barbiturates to neurotic patients particularly when a prescription allows the patient to acquire at once a quantity large enough to kill him

The development in the past few years of ultraviolet spectrophotometric methods for the estimation of barbiturates in body fluids has added much to our knowledge of poisoning by these drugs In our issue of Jan 28 Mr Broughton and his colleagues described their work at Oxford in the investigation of 36 patients during 1952–55 and similar studies have been described by Wright[3] of the London Hospital Broughton et al used a modification of Goldbaum's ultraviolet spectrophotometric method,[4] and this enabled the laboratory to identify and to estimate the concentration of barbiturates in tissue fluids within one hour thus making the information of practical value to the clinician Wright found that barbiturates were distributed fairly evenly throughout the body-water, and quite an accurate estimate of the ingested dose could be made from the blood concentration and the patient's weight The concentration of drug in cerebrospinal fluid was rather lower than that in blood which is further evidence that the old advice to drain the cerebrospinal fluid in barbiturate poisoning has nothing to commend it Estimations of the concentration of barbiturate in the urine are of no clinical value because large doses of barbiturate depress urine secretion The short acting and medium-acting barbiturates being largely destroyed in the body appear unchanged in only low concentration in the urine and the presence in urine of other chromogens interferes with the accuracy of the estimation Phenobarbitone is more easily detected but Broughton et al were unable to correlate its concentra-

Printed by Hazell, Watson & Viney, Ltd, London and Aylesbury—Saturday, February 25, 1956
Printed in Great Britain—Entered as Second Class at the New York, U S A, Office

d with malignant hypertension and congestive failure nd on one occasion he required treatment with an rtificial kidney for uræmia and convulsions After the operation, the transplanted kidney began to hyper-rophy, the patient improved rapidly, and his blood-ressure was reduced to a range of 130–160 mm Hg ystolic and 80–90 diastolic Because of the persistent nd mild hypertension, his two damaged kidneys were emoved 3 and 5$^1/_2$ months after the renal transplant, and is blood-pressure then fell to normal levels The patient s now in good health, his activity is unlimited, and he has no apparent physical disability Examination of the urine from the new kidney showed a proteinuria of 4 5 g per 24 hours but no other abnormality

Before the operation a geneticist determined beyond reasonable doubt that the twins were identical This was done on the identity of their anthropological, immunological, and physiological (ability to taste phenylthiocarbamide) characteristics when compared with their sibs Later, immunological and genetic similarity was proven by the crossed transplantation of small skin grafts between the twins The skin transplants took and when biopsies were taken a month later, they appeared to have survived as normal skin

At the operation the vessels of the transplanted kidney were grafted on to the recipient's hypogastric artery and common iliac vein The ureter was implanted into the bladder This site was selected because experience with 13 previous renal transplants in man had pointed out the disadvantages of the renal fossa and the right thigh as recipient sites The ureter was implanted into the bladder because experience in Boston with autotransplants of kidneys in dogs had shown that the organs survived permanently when the ureter was transplanted into the bladder rather than into other organs, when the autografted dog kidney deteriorated rapidly[26] Simultaneous operations were performed on recipient and donor in adjacent operating-rooms, and although the donor kidney was ischæmic for 82 minutes the entire organ became turgid and pink immediately the clamps on anastomosed vessels were released A ureteral catheter was left in the donor ureter until the 9th postoperative day when normal function of the donated kidney was proven beyond doubt by prompt excretion of injected indigo carmine

Identical twins are born approximately once in 350 births and there cannot therefore be many patients with renal failure who will be able to benefit immediately from this work But the fact that the operation is technically feasible should encourage those who are investigating the causes of failure in renal and dermal transplants in man and in animals These and other related problems were discussed at length at a Ciba symposium held in London two years ago[27] At the meeting of the Central Society for Clinical Research in 1954 Good and Varco of Minneapolis, reported successful transplantation of a homograft of skin in a child with agammaglobulinæmia[28] Since skin and kidney possess a common antigen,[29] it is reasonable to speculate that renal homografts might take in patients ill with this rare disease If agammaglobulinæmia can be produced artificially in patients with renal failure, it may provide the answer to renal transplantation in man On the other hand it may exchange one fatal disease for another

Annotations

ARTERIOGRAPHY IN BONE TUMOURS

EVEN after careful assessment of the history, the clinical signs, and the straight radiographs, it is often hard to say whether a particular bone lesion is malignant or not Many of these doubtful lesions are in children or young adults for whom a major amputation undertaken because of a wrong diagnosis of malignancy would be especially tragic Moreover, the pathologist is often unable to clinch matters because the biopsy specimen may not be typical of the whole In view of these difficulties, it is surprising that other ancillary methods of diagnosis, such as percutaneous arteriography, have not been used more widely The technique was introduced by Dos Santos et al[1] as long ago as 1932 Since that time there have been relatively few reports of its use in this way The introduction of less toxic contrast media, and recent work by Lasser and Von Schowingen[2] in America and Sutton[3] in London, may stimulate research and encourage the further application of arteriography in the diagnosis of bone tumours

Percutaneous puncture of the femoral or subclavian vessels is a safe operation in experienced hands, and a skilful operator can get successful results in over 90% of cases Puncture of the brachial artery is less satisfactory owing to its variable anatomy and the risk of inducing spasm In over 250 cases of percutaneous arteriography, Sutton encountered no severe or important complications He recommends 42% diodone, except for the brachial artery, where he uses a 35% solution Percutaneous arteriography is uncomfortable for the patient, who usually experiences a feeling of intense heat in the limbs, and the examination should be performed either under general anæsthesia or after adequate sedation

With rapidly growing malignant tumours an abnormal vessel pattern is often displayed The arrangement of these vessels differs strikingly from the normal orderly arborisation. There are more vessels than normal, venous channels can be seen more readily, and a 'tumour stain" is often distinguished Osteoplastic metastases do not usually show tumour vascularity but the osteolytic secondaries show varying degrees of abnormal vessel formation, similar to that produced by primary malignant tumours Osteochondromas usually leave the normal vascular pattern unchanged, but giant-cell tumours become diffusely opaque within three or four seconds of the injection, and the opacity persists for at least six seconds In some tumours of low malignancy, such as fibrosarcoma, Sutton saw no abnormal vessels In fibrous dysplasia the vessels are dilated but normal in distribution Lasser and Von Schowingen report that in Paget's disease there is no vascular abnormality, but in one such case they noted abnormal vessels, and the patient later died from neoplastic bone changes

"A GREAT PATIENT"

Ethel Wise was born in 1886 at Stratford, Essex During her 69 years of life she was admitted to the London Hospital 53 times, and she died there in April, 1955 She was "in service" until an accident in 1926 started her long odyssey of illness Rheumatoid arthritis, rheumatic heart-disease streptococcal septicæmia pernicious anæmia, carcinoma of the breast, X ray dermatitis and pulmonary fibrosis, these, with their complications and sequelæ, were the life of Ethel Wise 7 consultants and 32 house physicians cared for her in hospital She complained little, and endured all things After her death her last clinical clerk wrote her history,[1] and in a foreword Dr A E Clark-Kennedy, her physician, says

> "We read the obituaries of great doctors and surgeons but never I think of great patients Yet those of us who have been in practice for any length of time have all come across some great patients Some had been born great Others were great and some had had greatness thrust upon them By no stretch of imagination could Ethel Wise be said to have been born great but all who knew her remain convinced that she was by nature great and that ill health forced greater greatness on her In her body she taught us much about disease in her mind very much more about courage in the face of adversity'

It is good, in the midst of such things as occupied bed percentages problems of medical man power, morbidity

---

on Conditions in Iron Foundries, which had the late Mr H E **Chasteney**, H M Chief Inspector of Factories, as its chairman, led to the creation of the Joint Standing Committee The latter [6] has made many investigations into practical methods of dust and fume control, which are described and illustrated in its report Until 1943 the known cases of pneumoconiosis in iron foundry workers were few, and indeed, until the results of the survey by **McLaughlin** and his co workers became known, they were excluded from the compensation schemes for silicosis under the Workmen's Compensation Acts The difficulty about bringing them under such a scheme was partly due to the fact that hitherto the classical silicotic nodule had dominated the study of the pathology of the industrial diseases of the lungs Any case in which classical silicotic lesions were not found could not be diagnosed as silicosis and hence was not eligible for compensation The new pathological studies, however, showed that the main lesion in the lungs of iron foundry workers (particularly iron fettlers or dressers) was another type of nodule with a linear and radial pattern as opposed to the whorled arrangement of fibres in the classical silicotic nodule To this type of lesion **Harding**, **Gloyne**, and **McLaughlin** applied the term "mixed dust pneumoconiosis" or "mixed dust fibrosis" When it was established that iron foundry workers did contract pneumoconiosis they could be brought under the compensation schemes, and this emphasised the need for more intensive efforts to control dust and fume

The engineering section of the report deals, among other things, with the control of dust and fume in pedestal, surface, and swing frame grinding, in fettling with the pneumatic chisel, and in "*knocking out*" *the castings from the sand* moulds in mechanised, light, and heavy and jobbing foundries The methods of dust control by water are described and in particular a new type of wet decoring bar As regards cupola furnaces, various types of spark arresters are discussed, and also the evolution of, and control of, carbon monoxide and sulphur dioxide Original work in this connection has been done on heating and core stoves, and also on mould drying by various appliances The electric mould dryer is regarded as the best type, because less fumes and gas are evolved when it is used

The Joint Standing Committee has also given attention to the irritable and objectionable fumes which may be given off when certain kinds of binders are used in core making, such as synthetic resins and oils New foundry processes such as shell moulding and the carbon dioxide process of mould and core-making are mentioned. These two processes are spreading rapidly in foundries and are likely to revolutionise the industry Because there is less burning on of sand on the moulds, the risks associated with the fettling of castings are reduced, but the new methods might bring with them other health risks

We welcome the report as an indication that much time and energy has been directed to minimising the risks to life and limb of the workers of one of Britain's most important basic industries And it is pleasing to note that the effort is a concerted one by employers, trade unions, and Government departments, and by doctors and engineers

Mental Health and the Schools

In recent years we have come to understand something of the relation between the training of children and their health in later life Psychological investigation has displayed the primary importance of the parent-child relationship especially in the early years, and we are now beginning to extend this scrutiny to the child's relationships with *subsequent parent substitutes* of whom the teacher is commonly the *most* influential For a very long time schools were adult centred pupils were expected to behave as though they were merely undersized adults and obliged to conform completely to grown-up standards of behaviour But the insights which psychologists and brilliantly intuitive educational practitioners like Madame Montessori have turned upon the learning situation and the teacher child relationship have already wrought a great change Schools are now progressively child-centred, and norms of achievement development, and discipline are related to pupils' real needs and abilities But this advance is of course by no means universal, and there is room for further experiment Such conferences as the one organised by Unesco in Paris in 1952, of which a report is now published[1] show how much has still to be learnt and done

A smaller follow-up study,[2] dealing exclusively with the periods of possible stress in British primary school outlines the steps needed to safeguard younger children and again draws attention to the conception of education *as a partnership between home and school, parents and* teachers Its authors have no doubt that parent teacher associations help to promote such a partnership, enabling teachers to pass on to parents "something of what they have learned   for in regard to their own children parents are incomparably the most influential teachers" While this latter statement may be questioned—not least by parents—there can be no denying that parent teacher associations are often valuable Some feel, indeed, that it is one of the weaknesses in the present British system that in many parts of the country the decision whether or not an association shall be formed is *left* entirely *to the* discretion of the head teacher, whose own faulty emotional attitudes *may prejudice him against too* close a partnership with the parents of his pupils But as the advantages of such a partnership are demonstrated, and it becomes more familiar, the opposition is likely to fade

The *British report directs special attention* to the stress and strain that the selective nature of the 11+ transition period has on primary school life The coming secondary school entrance examination looms ahead, like a huge *question-mark overshadowing a child's present* and future Where he comes from an ambitious and over-anxious home the strain of this period may become excessive and lead to mental breakdown and acute anxiety Parents, children, and teachers alike become involved in the general anxiety, *each stimulating* the other until the child is so worried that he is unable to do himself justice in the examination itself There will be no way to avoid this time of stress and strain in primary school education until the system itself is modified Fortunately there are signs that some local education authorities are taking steps to reduce the feelings of inequality between pupils with differing gifts and between schools with different curricula Bilateral, multilateral, and comprehensive schools are possible means of reducing this tension and of killing the purely snob value of a grammar school education An improved system of selection and more accurate psychological assessments would also go a long way to produce a fairer outcome and to allay widespread anxiety But, as the report concludes, "a reduction in the number of children for whom any one teacher is responsible is perhaps the most urgent single reform in education in England today Its urgency is evident when one pauses *to* realise that the future of the nation depends increasingly on the quality of the day-to day teaching and the personal relationships of the teachers and the children in our schools intestinal disease, sometimes producing symptoms similar to those of cœliac disease

[2] Periods of Stress in the Primary School London National Association for Mental Health 1956 Pp 38 3*s*

Over the last three years I also have observed in my cases of acute infectious disease in young children that some have developed, during convalescence, symptoms like the early manifestations of cœliac disease These symptoms respond dramatically (usually within two or three days) to a gluten free diet and reappear when a premature return to normal diet is made Typically, a child between 1 and 5 years of age becomes naughty and difficult a few days after the onset of an acute infectious illness such as measles or gastro enteritis He is irritable, negativistic, and spiteful, sleep is disturbed and he wakes up many times in the night and often screams, his appetite is poor, he fails to gain weight, his abdomen is often distended, and the stools resemble those of cœliac disease This condition, if left untreated, usually rights itself after a month or two, but may last for much longer, in which case slight petit mal like attacks may develop, in addition to worsening of the other symptoms Even at this stage, a gluten free diet can still cause complete remission of symptoms

The adult equivalent of this syndrome seems to be the headache, insomnia, and depression that commonly follows infectious illnesses such as influenza These three symptoms are often associated with irritability, abdominal distension, and pruritus ani The response of all symptoms to a gluten free diet is prompt in most cases, and they reappear if the diet is discontinued too early The animal counterpart of these syndromes may be canine hysteria

Circumstantial evidence suggests that these conditions are caused by an allergic reaction to an amino acid digestion product of wheat flour affecting nerve, intestinal, or other cells temporarily damaged by the infective process Unfortunately skin tests are no help in establishing the allergic basis of these syndromes, any more than of cœliac disease itself If the conditions are in fact allergic the allergens involved must be blood borne, because of the diversity of the manifestations, therefore the allergens must be digestion products of wheat-flour rather than the wheat proteins (glutenin and gliadin) themselves The exact nature of the allergen remains obscure, but my observations lead me to believe that it is closely connected with the "staling" process of flour and flour products

Some of this work has been published in detail,[2] and I propose to publish the rest shortly I hope that others will be able to observe similar cases and undertake a controlled study

Hove Sussex **GUY DAYNES**

LEPTOSPIROSIS AMONG BRITISH TROOPS IN MALAYA

SIR,—The views expressed last week by Captain Clein are to be respected in that they represent his own personal opinion I feel I should point out, however, that at present the weight of specialist opinion in the Army Medical Services is that penicillin is of little value in the treatment of leptospirosis as encountered in Malaya and Singapore

W A D DRUMMOND
Deputy Director General
Army Medical Services

War Office
London S W 1

HYPERTROPHIC PULMONARY EMPHYSEMA

SIR,—Although Dr Oswald terms your leader (Jan 7) as "conventional," his own letter (Feb 4) might surely be more justly described by this adjective For the whole difficulty of the interrelationship between chronic bronchitis and emphysema lies in the most *unsatisfactory nature of the* conventional explanations

The clinical and pathological problems were well described by Dr Samual Gee sixty years ago To suggest that the observation of "repeated infection" in chronic bronchitis thereby resolves its aetiology begs the difficult questions Does this infection suddenly start, de novo, in a previously healthy lung? Have the changes in lung function, recently demonstrated in normal people with increasing age, any importance in this development? Why do some patients produce a considerable amount of sputum for years without emphysema developing, while others first seek advice when they have a considerable degree of lung destruction, and tell us that they very rarely cough?

So far as I am aware there is no authority for Dr Oswald's statement that the most useful pulmonary function test in practice is the measurement of the oxygen saturation of the blood before and after exercise In my experience this is one of the least useful tests in the assessment of emphysema To remark that the accurate diagnosis of emphysema is largely academic, is premature, since we will be aware of the problems only when accurate diagnosis is possible, there is little doubt that the measurement of lung damage by tests of function has a major part to play in this task

St Bartholomew s Hospital,
London E C 1 **D V BATES**

BENZATHINE PENICILLIN

SIR,—May I draw your attention to a possible objection to the use of long acting benzathine penicillin preparations, particularly injections said to give therapeutic blood-levels for up to one month I am concerned about the chance of an allergic reaction developing soon after injection, yet there will remain in the body penicillin potent for days or even weeks Hitherto no serious reaction to these injections has been reported, but it would seem that a special hazard may exist

Mayer de Rothschild Hadassah
University Hospital, Jerusalem **ELI DAVIS**

FAMILIAL HEMIPLEGIC MIGRAINE

SIR,—Dr Blau and Dr Whitty have written a most interesting paper on this subject[1] However, their statement that "The condition appears to be inherited through a recessive gene " is correct only if they change the word "recessive" to "dominant"

Department of Medical Genetics
Montreal Children s Hospital,
Quebec, Canada **JULIUS METRAKOS**

*** This letter has been shown to Dr Blau and Dr Whitty, who write "We are grateful to Dr Metrakos for drawing attention to our error Inheritance appears to be by an irregularly dominant gene"

HOMOSEXUALITY

SIR,—Dr Learoyd's criticisms (Feb 4) of Dr Comfort, and his oblique championship of the B M A report, would have carried more weight if he had been more objective Had he, for instance been able to adduce statistical evidence to support the claim that punitive measures such as martyrdom, witch-hunting, inquisitions, pogroms, and the odium attaching to illegitimacy had significantly reduced the numbers of Christians, witches, heretics, Jews, and bastards, then, by parallel argument, he might have developed a less gratuitous case against Dr Comfort Alas for sophistry! History, rather perversely, tends to show that whereas persecution supported by legislation has ever achieved but little, the repeal of some *of the relevant civil laws has, in most cases, at least mitigated* the associated evils

London N W 3 **PHILIPPE BAUWENS**

"MUNCHAUSEN'S SYNDROME"

SIR,—On the evening of Feb 2 a young Irishman, with a crew cut, claiming to be a ship's radio officer and ex-mental nurse, appeared in this hospital He said that two hours previously right postauricular pain and unsteadiness of gait had developed

He was afebrile, with a right facial palsy, a healthy right mastoid cavity, and papillœdema of the right optic disc, although this was not easily seen because of continual to-and-fro movements of the eye He bore the scars of many operations on the right side of his skull, with a recent endaural scar which he claimed was due to a mastoidectomy in Dublin nine months before This identified him as the man described by Dr Robson last week and by earlier correspondents

Despite heavy sedation, he was troublesome throughout the night and the following morning During the afternoon he became violent and aggressive Dr J T Hutchinson, the visiting psychiatrist, considered him to be a hysteric rather than a malingerer, he was remarkably suggestible He had apparently lost 4 stone in weight, and it was difficult to see the cause of his behaviour He was admitted to a mental hospital that day

Dr Mouchot continues, "how and where to resettle the wine producers, publicans, still owners and others who would become redundant, it is childish to expect politicians to do anything" Meanwhile, the consumption of alcohol per head in France is the highest of any nation (Italy is second) both absolutely and in relation to national income The total consumption in France is three times that in Great Britain

Lest this comparison lead to unjustified feelings of complacency, it is as well to remember that (according to the latest available returns) no fewer than 50,000 persons were convicted of simple or aggravated drunkenness in 1953 before magistrates' courts in England and Wales

STREPTONIVICIN

A NEWLY discovered antibiotic, streptonivicin (albomycin, 'Albamycin'), is produced by an actinomycete, *Streptomyces niveus* (*Actinomyces subtropicus*) By comparing ultraviolet absorption curves, Welch and Wright[1] have shown that streptonivicin is identical with two other new antibiotics, cathomycin ('Cathocin') (obtained from *Streptomyces spheroides*) and 'Cardelmycin' (crystallinic acid) Streptonivicin has been known to Soviet workers for about five years but has only lately become available in the West It was first isolated in 1951 by Gause and Brazhnikova,[2] of the Institute for Antibiotic Research in Moscow They obtained it from cultures of *Actinomyces subtropicus*, and named it albomycin The antibiotic has been investigated in the United States under the name streptonivicin It inhibits the growth of gram-positive cocci, chiefly pneumococci, staphylococci, and *Streptococcus pyogenes*, and what is equally important it inhibits the growth of sensitive organisms resistant to other antibiotics, including penicillin, streptomycin, the tetracyclines, and erythromycin[3] Resistance to streptonivicin can, however, develop It is also effective against a number of gram negative bacteria, such as Friedländer's bacillus and the coli dysentery group, klebsiella, *Aerobacter aerogenes*, and *Micrococcus pyogenes* (which is highly sensitive) Rather less sensitive are meningococci and *Hæmophilus pertussis* *Mycobacterium tuberculosis* is insensitive The pure substance inhibits the growth of staphylococci at a dilution of 1 in 700 million, the figure for penicillin is 1 in 80 million Brazhnikova et al[4] found that streptonivicin is a basic compound forming an amorphous red sulphate, readily soluble in water, slightly soluble in methanol, but insoluble in other organic solvents The pure substance contains 4 16% iron, which can be removed by treating with acetone containing hydrochloric acid, but this treatment reduces its antibiotic activity It is thought that the iron is chelated to the hydroxy group in serine, which is part of the molecule On hydrolysis a number of amino acids are formed Streptonivicin appears to be a complex metal containing polypeptide with a molecular weight of about 1300 Chromatography shows that the constituent amino acids are ornithine, serine, glutamic acid, alanine, glycine, and another unidentified one A solution of the antibiotic is stable for only two days[5]

Since streptonivicin inhibits the growth of sensitive bacteria only in the presence of oxygen, it may interfere with the oxygen-transporting iron containing enzyme in susceptible bacterial cells[6] Its chemical structure is possibly related to this enzyme, with which it may compete in a respiratory-enzyme system Pharmacologically streptonivicin seems to be inert, it produces no local reactions, and, like penicillin, is of extremely low toxicity A mouse, for example, tolerates a dose of 50 million units per kg body weight No effect on the liver, kidneys, or hæmopoietic system has been observed in patients given the antibiotic A remarkable property of streptonivicin is its ability to form a reversible complex with serum proteins, which facilitates its circulation in the body[2] This complex has chemotherapeutic properties, but unfortunately it interferes with the assay of the antibiotic in the blood The serum-proteins, which bind about 90% of a single dose of streptonivicin, must be precipitated by trichloracetic acid before the assay is made The protein streptonivicin complex apparently dissociates in vivo, because it is active when injected intraperitoneally into mice infected with pneumococci or dysentery bacilli, whereas in vitro it has no effect on these organisms Since this complex is not readily excreted by the kidneys, an initial dose of streptonivicin is slowly excreted After repeated injection the amount excreted rises sharply because the serum proteins have become saturated and free antibiotic circulates in the blood The free streptonivicin is excreted for six to eight hours after injection[8] The antibiotic is absorbed in man if given by mouth, and doses of 0·1–0·5 g six hourly produce effective blood levels There is, however, great variation in the concentration in the serum, a fact for which there is no ready explanation The drug appears in the bile and in ascitic and pleural fluids, but not in the cereb spinal fluid[5]

Mice infected with 500,000 lethal doses of pneumococci show 100% survival-rates after a single subcutaneous injection of 750,000 units of streptonivicin per kg Mice infected with various strains of staphylococci and hæmolytic streptococci have also been successfully treated There seems to be a synergistic action with penicillin and streptonivicin Turning to the clinical use of streptonivicin, in Russia[2,4] it has been used mainly in the treatment of infections by pathogenic cocci, particularly when they are penicillin resistant Intrathecal injections of 100,000–200,000 units gave good results in the treatment of meningitis due to susceptible organisms Other uses include the treatment of peritonitis and surgical infections, and penicillin resistant prostatitis and gonococcal urethritis We do not know of any other clinical reports and await further news with interest

DIRECT ACTION

On Monday it was stated that about 10,000 nursing staff in 33 mental hospitals have now declared that they will no longer work overtime They have done this to express their dissatisfaction with their pay and with the conditions of their service, under which longer and longer hours are demanded of a dwindling staff who (unlike people in most other occupations) do not get a higher rate when they come early or stay late

Working conditions cannot be substantially improved until there are more nurses, but it is hard to find new recruits for an aggrieved profession, and even harder to hold them In some hospitals, indeed, the turnover of nurses must almost rival the turnover of patients It is reported,[9] for instance, that in the Manchester region six hospital management committees, with an establishment of 2929, in one year accepted 1842 recruits, but were worse off at the end of it because they had had 1891 resignations Nor will incidents such as the unfortunate demonstration by nurses at the Ministry of Health's exhibition at Manchester speed the recruiting drive With the best will in the world on all sides, it will need patience and a different climate of public opinion to provide the extra staff that alone will enable these conditions to be greatly changed

On the other hand it is obvious that the nurses' other and closely related reason for dissatisfaction—the insufficiency of their pay—could, at a cost, be adjusted immediately, and they complain of the slowness of negotiations in the Whitley Council That they are not alone in this complaint was shown again in an adjournment debate[10] in the House of Commons when the Whitley Council machinery of the National Health Service was criticised Negotiations, Mr Arthur Blenkinsop declared, were delayed because the Treasury insisted that no suggestion should be put forward by the management side without its prior approval He warmly supported the recommendation of the Guillebaud Committee that the representation on these councils of regional hospital boards and hospital management committees should be increased At present, as Mr. Herbert Butler put it, the Ministry of Health had interposed Ministry and Treasury officials between the hospital authorities and the council, and in consequence the machinery did not move fast enough to deal with day to day problems Meanwhile, not only in mental hospitals, management committees grow more and more uneasy at their inability to offer rates of pay bearing a reasonable relation to those to be had at the nearby factory or airport

We note with deepening anxiety the tendency of people in the health service to adopt the mental attitudes and techniques of organised labour, which are often irreconcilable with those of a profession But in this case, as so often in industry, part of the responsibility for direct action lies with those who tend to delay necessary concessions until these are made urgent by a threat

higher cerebral centres but from the midbrain" I wrote (*Lancet*, 1950, i, 881) "My observations (in my work with mentally handicapped children) have strengthened my belief that many mental defects are the result of unrecognised birth hæmorrhages affecting tributaries of the vein of Galen and injuring ganglia of the mesencephalon and telencephalon" And where did Dr Bourne read that "the vital lesion lay constantly in the corpora quadrigemina and the lateral geniculate bodies"? I wrote "Pathological changes in the above mentioned ganglia (i e, the corpora quadrigemina and the corpora geniculata) and in their afferent and efferent tracts may play one of the most important roles in the causation of mental defect" (*Brit med J* 1953, i, 936) And in a later letter (*Brit med J* 1953, ii, 392) I stated explicitly "My topographical reference embraces the whole length of the visual and auditory pathways from receptor organ to cerebral cortex This shows that my hypothesis is not primarily concerned with the actual anatomical level affected by the impairment, but with the circumstance that mainly or even exclusively disturbances affecting to some degree the integrations of the visual or auditory system will lead to a mental defect" One can hardly be more precise in regard to the widespread possibilities of localisation —LISE GELLNER, M D (St Lawrence's Hospital, Caterham, Surrey)

Deaths During Anæsthesia —In your annotation (Jan 21) you say that "about 8 million" anæsthetics were given in the hospitals of England during 1954 The figure is presumably taken from the Ministry of Health's report, and owing to your omission of the words "alone or in combination" a total considerably in excess of the true one has been achieved The correct total is obtained by multiplying the total number of operations for the sample week—56,062—by 52 (or more accurately 51 owing to bank holidays) This gives a grand total of some 2,860,000 operations for the year, each operation involving the use of about 2 3 anæsthetic agents (oxygen having been excluded as an anæsthetic) This total of 2,860,000 anæsthetics does not of course include operations in nursing-homes, maternity cases, and dental anæsthetics, *and I do not suppose that the number of these can ever be computed* But it is very gratifying to learn that the total number of deaths under anæsthesia continues to diminish —MASSEY DAWKINS, F F A R C S (London, W 1)

Intragastric Milk Drip —I must apologise to Dr Watkinson and Dr Chandler (Jan 28) for not quoting their paper more fully, but this seemed unnecessary as I was merely investigating the use of a Ryle's tube in predicting massive gastrointestinal hæmorrhage They wrote (*Lancet*, 1953, ii, 1170) "The bedside observation of bloodstaining in the aspirated specimens was useful because further hæmorrhage could be detected before other clinical criteria had indicated its presence" Unfortunately, this is not supported by my experience (Jan 14)

I was surprised to see the resurrection of that hoary old red herring, the overall death rate I thought that this had been decently buried in 1947 (F Avery Jones, *Brit med J* 1947, ii, 441, 477) Suffice it to say that in Chandler and Watkinson's published series 8 5% of the patients were older than 70, in my series 19% of the patients were older than 70, and of the 8 deaths 6 were in this group —A M DAWSON M R C P (Central Middlesex Hospital, London, N W 10)

"Infectious Roseola" —Dr Fletcher reports (Jan 7) that in Sarafand in August and September, 1941, 'some fifty cases of what I termed (for want of a better name) 'infectious roseola occurred Similar small outbreaks were noted in the surrounding district" During the same period in Tel Aviv, notably in the suburbs, I saw *some hundred patients* with apparently the same disease (We knew of the outbreak in Sarafand) We described the outbreak as "an unknown epidemic infectious disease" (M Leffkowitz, *Harefuah* 1942, 22, 3) The picture was identical with that reported by Dr Fletcher The incubation period was 3½–5 days We, too, suggested that the cause was a virus In the years 1950–53, particularly in the same districts there were further outbreaks (P Radt *Harefuah*, 1955 49, 41) The evidence indicates that the disease was caused by West Nile virus (E Olejnik, *Bull Res Coun Israel*, 1952 2, 210 H Bernkopf, *Harefuah*, 1953, 45, 101 N Goldblum et al *Amer J Hyg* 1954, 59, 89 M Benjeh N Goldblum, *Harefuah*, 1955, 48, 58) Accordingly the disease has been called West Nile fever —M LEFFKOWITZ M D (Belinson Hospital, Petah Tiqva, Israel)

Unfair to Surgery —In your issue of Jan 14 (p 107) tw doctors said that after having several feet of gut removed many years ago for regional ileitis they were "as fit as fiddl May I add that one of them, not so many months after h titanic operation, climbed the Schreckhorn by way of th N W arete I submit that he was then as fit as ten 'cellos —A E STEVENS M D (Jersey, Channel Isles)

Anticoagulants in a Hot Climate —In reply to Dr Merker and Miss Scholtz (Feb 4), I would point out that the Egyptia summer is much warmer than that at Cape Town (12–22 C At Suez the temperature may be as high as 41°C In patien on maintenance doses of phenylindanedione bleeding ma occur only on very hot days The maintenance dose of th drug I use is larger, as I aim at a prothrombin index of 10–30 and not 40–60% I agree that moderate heat (12–30°C) do not affect the maintenance dose of phenylindanedione —Ima TAWFIC, M D (Suez, Egypt)

Homosexuality —Dr Tuthill (Feb 11) uses the wor 'purpose" in relation to sex codes, and implies it in oth illustrations Whose purpose? Are we not often guilty of unwarranted abduction of this word from another system? Do we not usually mean "function"? Sex codes have maintained "the family as a social unit" that, from anthropological study, has evidently been one of their functions But whose purpose, whose intention, is it that they should? That surely, is another question altogether, consideration of which may throw a larger light on all cod by which they may be seen to fail or succeed in fulfilling a good or bad function —J N COZENS HARDY, B M (Holt Norfolk)

Inguinal Herniorrhaphy —Mr Doran has asked (Feb 4) how the conjoined tendon contributes to the integrity of the inguinal canal without literally acting as a shutter May I suggest that the conjoined tendon muscles do this by resistin anterior (or posterior) displacement of the "primary fixed point This prevents upward displacement of the "arch" It is perhaps better to regard the conjoined tendon as a 'partly closed shutter" in a state of dynamic equilibrium, tending to maintain its vertical position in the face of varying disruptive forces In this sense, the shutter like action may be said to occur, though paradoxically it moves little if at all Unchecked, the arch would rise as much as an inch in a person of average build This does not happen of course, and the function of the conjoined tendon must be deduced from what does not happen If this is so suture of conjoined tendon to inguinal ligament may so far displace the arch below its position of equilibrium that the muscles of the conjoined tendon would themselves tend to pull the arch upwards This effect should be only partly compensated for by relaxing incisions in the rectus sheath —J F ROBINSON M B (London, W 11)

Obituary

Mr G E NELIGAN

George Neligan was one of those men who give life to institutions and the corporate spirit of old students of the London Hospital owes much to his example in treating any Londoner as a personal friend He went to the hospital from Oxford in 1907, qualified in 1910, and was surgical registrar in 1914 Returning to the same post in 1919, with a Military Cross, he became assistant surgeon ("Howard and Neligan") in 1922, *specialising* in urology He did much to organise and build the students' hostel, and in the late war he lived in the hospital with the title of medical superintendent—a cheerful and reassuring figure After his retirement to Walmer in 1951, he was brought back to preside at the London Hospital dinner in 1953 when he was given an ovation The hospital and its students, it was said, had never had a better or more generous friend in all his years his attitude had been 'with malice toward none and charity toward all" He died at Folkestone on Feb 24, aged 71

We regret to record also the death of Mr HAROLD KING D SC, F.R.S, formerly of the National Institute for Medical Research

The Death Penalty

THE practice of taking the life of one who had taken the e of another originated in primitive societies as an act family vengeance, and this reprisal has persisted in me communities as vendetta In Britain the death enalty is a solitary instance of punishment matched ith crime Last week the House of Commons resolved, n a free vote and against the Government's advice, that uch punishment should be abolished or suspended

The issue between the defenders of this penalty and 's opponents has now been narrowed to a single question—whether its application has a unique deterrent ffect In the debate MAJOR GWILYM LLOYD GEORGE, the Home Secretary, declared ' Let me say emphatically hat I believe capital punishment to be justified only if it s likely to reduce the amount of murder " The Royal Commission on Capital Punishment found "no clear evidence in any of the figures we have examined that the abolition of capital punishment has led to an increase in the homicide rate, or that its reintroduction has led to a fall " But it added "The negative conclusion we draw from the figures does not of course imply a conclusion that the deterrent effect of the death penalty cannot be greater than that of any other punishment It means only that the figures afford no reliable evidence one way or the other "

There being no good evidence that hanging murderers checks the number of murders, the case for discontinuing this rough justice seems to us unanswerable Firstly, by ending the life of a murderer we impose gross suffering on his relations, before and after the execution Secondly, in a trial for murder, juries, aware of the grim decision before them—and perhaps of the conceivable risk of exterminating an innocent victim—are reluctant to bring in a verdict of guilty (A law which may thus be imperfectly applied is a bad law Nor is the final decision by one man regarding reprieve fair to the prisoner, whose life depends on the decision, or to the Home Secretary, who must make the decision) Finally, our society damages itself by giving its warrant to the killing of any of its members, and this damage is made the worse by newspaper accounts of the final days and hours of the murderer's life, which, like the public executions of bygone days, satisfy and promote a morbid appetite

At the start of the 19th century over two hundred crimes were punishable by death The curtailment of the death penalty was accompanied by widespread forecasts of increases in crime These forecasts were not fulfilled We welcome the Prime Minister's assurance that he will seek to give effect to the Commons decision, and we hope that when the time comes the House of Lords will bear in mind the country's growing uneasiness about this grotesque legacy from our forefathers

The Patient and his Cell Nuclei

THE development of a new and important diagnostic technique creates fresh difficulties, even though it contributes to the solution of existing ones There is, for example, the practical problem of ensuring that the new method when it has left the hands of its pioneers and is put to routine use in laboratory or ward, is performed and interpreted by those who are aware of its difficulties and its limitations For these reasons Professor BARR's views[1] on the conclusions to be drawn from the cytological tests of sex are particularly welcome He reminds us that it is too early to assume that the "female" sex chromatin is in fact derived from two X chromosomes, and therefore we should not yet use the expressions "chromosomal sex" or "genetic female" or "genetic male" He proposes the sensible alternative, for use in the clinic or outpatient department, of "chromatin positive" (female) or "chromatin negative" (male), in order that no suggestion can, by mischance, be conveyed to any patient that the "maleness" or "femaleness" of the body-cells is at variance with sexual anatomy—and, he might have added, with the patient's body-image and inner concept of sexual status Nor should this information be deliberately given to the patient or to relatives GRUMBACH et al[2] believe "it is most important that the patients and their families should not be informed concerning their chromosomal sex when a male chromatin pattern is found, in view of present day misconceptions of the importance of chromosomes in determining psychosexual outlook " This opinion has the authority of the senior author, LAWSON WILKINS, whose experience of the sexual deviations of children, chromosomal and hormonal, is unrivalled

Few will dispute this advice, but the reason for it should perhaps be further emphasised The sexual orientation of an individual is not determined either by the sex chromosomes or by the hormones, and still less by the chromatin in the cells of the skin It would be very unwise to attempt to change the psychosexual habit which has been established through the years of growth or even to convey information which will challenge the integrity of this personal image HAMPSON et al,[3] working in Wilkins's clinic, studied 11 girls and women with gonadal agenesis who were chromosomally male, and all of them "were found unequivocally to fulfill the cultural and psychological expectations of femininity The salient finding to emerge from the study was that a person's conviction of himself as a man or herself as a woman—the gender rôle and erotic orientation—is a variable quite independent of genes and chromosomes " Cytological sexing is therefore another of the findings which the doctor should not pass on to patients and their relatives, for its exact significance will not be understood and its real importance may be misconstrued The doctor's duty is to shoulder, on behalf of his patient, the diagnostic and therapeutic responsibilities involved

In the management of hermaphrodites, female pseudohermaphrodites, male pseudohermaphrodites, and patients with gonadal dysgenesis, the new methods have done much to increase diagnostic precision, and they enable a rational plan of treatment to be made in the first few weeks of life, when these anatomical deviations

GLUTEN TO BLAME ?

In a letter in our last issue, and in more detail at a meeting f the section of general practice of the Royal Society of ledicine on Feb 15, Dr Guy Daynes described what he called he "pre coeliac syndrome", a disturbance of convalescence in oung children and possibly also in adults He has noted over 0 examples in children in his own practice and clinics in 2½ years Most of those affected were between 1 and 5 years old They were just getting over an acute infection when they began to be irritable and spiteful, to wake screaming in the night, and to lose appetite and weight At the same time the stools became bulky The child usually recovered slowly but spontaneously in a few weeks But, Dr Daynes found, recovery was complete in two days when the child took a diet containing no wheat flour, and relapse was equally dramatic if this diet was stopped too soon Dr Daynes thinks that adults with insomnia, headache, and depression also respond well to such a diet, and suspects that the gluten of the flour is toxic, because it is the gluten which is altered by the chemical improver, agene, with the production of methionine sulphoximine, which causes hysteria in dogs And it is well known that true coeliac disease improves promptly when gluten is excluded from the diet

Some speakers at the meeting felt that Dr Daynes had carried his views rather further than the evidence warranted It was pointed out that there was little apparent similarity between canine hysteria and coeliac disease Prof A C Frazer remarked that true cœliac disease varied considerably in its manifestations from patient to patient, if the condition Dr Daynes described has a similar origin one would expect the same sort of wide variation

The exclusion of wheat flour means the exclusion of all bread and pastry, sausages, chocolate, tinned meat-loaf, and much else, and this obviously alters the starch and roughage content of the diet Before gluten alone can be convicted, the evidence must show clearly that the addition of pure gluten causes a relapse The question of vitamins and calcium must also be considered Individuals may differ considerably in their vitamin requirements Hersov[1] recently described an English schoolboy who had pellagra with mental symptoms while eating fairly normally—apparently because his need for nicotinamide was far higher than normal What happens to the intestinal flora during acute infection and convalescence, how glands like the pancreas respond to virus infections, and how the individual's biochemical requirements vary, are little studied but important matters General practitioners are often in the best position to observe the phenomena of convalescence, and to delineate the syndromes which may appear But the clinical pathologist is needed when it comes to disentangling the underlying causes A syndrome may be the final manifestation of several distinct pathological processes, and only the laboratory can differentiate them

THE EMBOLIC CANCER CELL

THE lymphatic spread of cancer is so common and so apparent that its detailed study may not get the attention it deserves In his book on the spread of tumours, Willis[2] described with great accuracy the morbid anatomy of 500 necropsies he had himself performed and he made an extensive, though admittedly incomplete, survey of the literature of the spread of cancer Some further work is now in hand in Philadelphia where a group of workers is studying experimentally the spread of cancer in the lymphatic system Their first task was to find a reliable experimental technique[3] By injecting suspensions of cancer cells into the afferent lymphatic vessels in the calf of the rabbit, they were able to show that tumour-cell emboli, on entering the regional lymph gland, were immediately held up in the subcapsular sinus and did not reach the hilar sinus, or escape from the gland Moreover, they found that at least three weeks (and sometimes longer) elapsed before tumour cells escaped from the lymph gland. This did not occur until the gland was almost completely replaced by tumour, at which stage cancer cells might spread from it to the blood stream. Zeidman et al[4] then tried to find out whether it was possible to attack secondary deposits in the lymph glands by injecting chemotherapeutic agents into the afferent vessel, but they were unable to demonstrate any lymphatic channels in such carcinomatous deposits The next extension of the work[5] was to ascertain what happened to tumour cells injected into the thoracic duct In all the rabbits so treated many pulmonary tumours developed, owing to the direct passage of tumour cell emboli from the duct to the veins, and in all but one secondary deposits appeared in mediastinal and intercostal lymph-nodes, despite the fact that there was no obstruction to the thoracic duct at its entrance to the venous system By injecting dyes into the thoracic duct, it was shown that channels pass from it to the lymph-glands When tumour cells leave the thoracic duct and lodge in the glands, they are found in the subcapsular sinuses, and it seems therefore that they are taken there by true afferent vessels This was also the case when *tumour cells reached* the left supraclavicular glands Zeidman et al conclude that tumour cells reach thoracic lymph glands more commonly by direct spread via afferent lymph vessels than by retrograde embolism Thus Troisier's sign of enlarged supraclavicular glands may be explained by the direct passage of tumour cells from the thoracic duct to the glands, without the intervention of retrograde embolism aided by obstruction or of direct extension through the wall of a cancerous thoracic duct

These experiments remind us that the lymph glands are the first barriers to the embolic spread of tumour cells It would be well to consider what means might be used to increase the effectiveness of this lymphatic barrier by chemicals or hormones One grave objection to the use of radiation for the treatment of cancer already established in lymph glands is the fact that adjacent unaffected lymphoid tissue is thereby depressed Should we not do less chasing of the hare from behind and make more effort to trap it from in front

CAVERNOUS PORTAL VEIN

PROGRESS in the surgical treatment of portal hypertension has reawakened interest in the various causes of portal obstruction Among the less common is the so called cavernous transformation of the portal vein Although the first example was reported in 1868[6] and only 22 further case reports appeared in the next sixty years,[7] two recent accounts,[8,9] based on 6 and 4 cases respectively, probably give a truer impression of its frequency

In this condition, the naked eye appearance of the structures in the portal fissure is characteristic The portal vein itself is usually unidentifiable amongst the sponge like mass of vessels This apparent replacement of the portal vein by a cavernous angioma usually extends in both directions, upwards into the liver along the portal tracts and downwards into the hepatoduodenal ligament But histological examination, especially with elastic tissue stains, shows that the portal vein is still present but obscured by thrombotic obstruction and recanalisation of its lumen and by the mass of collateral vessels around it

The clinical picture is remarkably uniform and is, in the main, what one would expect from a slowly developing portal obstruction Hæmatemesis from œsophageal varices is usually the presenting symptom, although it is often preceded by upper abdominal pain of varying severity Ascites is almost always absent—a finding in harmony with the present view that ascitic fluid is produced almost exclusively within the liver as a result of obstruction to its venous outflow[10] Jaundice is rare and there is seldom any evidence of impaired liver function The spleen is enlarged, often considerably so, and hæmatological indications of hypersplenism are common, although the anæmia is more probably due to the recurrent hæmatemeses Almost inevitably the illness ends fatally within a few months or years of the clinical onset—often when extension of thrombosis into the superior mesenteric veins leads to infarction of the small bowel

Three views have been advanced to account for this anomaly The first regards the lesion as a tumour-like overgrowth of vascular tissue corresponding to cavernous angiomata in other parts of the body The second regards it as a developmental abnormality comparable to the cavernous type of portal vein found in amphioxus and some of the cyclostomes The most should be given intravenously as soon as possible, the initial dose should be 4 g, and this may be enough or may need to be repeated later If fibrinogen is not available, blood can be given, taking 1 litre of blood to correspond to 1 5 g of fibrinogen The American workers agree that in all these patients the uterus should be emptied as soon as possible if labour does not ensue within twelve hours of induction, since the fibrinogen level always rises within forty-eight hours of delivery If treatment is to be effective, it must be given promptly, so some method for the quick assessment of the fibrinogen level in the plasma is needed **Barry** et al [8] give details of a method for a rapid but rough assay based on an original method of **Schneider**, and also of a rapid biuret method, devised by **Shea**, which gives a rough quantitative answer in ten minutes and a 90% accurate estimation in thirty minutes **Pritchard** and **Ratnoff** [7] describe a very simple "clot observation test", blood carefully withdrawn from a vein is run into a small tube containing a little bovine thrombin (now commercially available) Normally a firm clot should form in a few seconds, in hypofibrinogenæmia a clot may form, but it soon retracts, spontaneously or on tapping the tube, into a small ball from which most of the red cells are extruded Once the diagnosis of hypofibrinogenæmia is established, emptying of the uterus should be carefully considered, though the case-records suggest that dangerous hæmorrhage is not inevitable If bleeding has to be dealt with, the best treatment is certainly the intravenous injection of fibrinogen as soon as possible As most of the National Blood Transfusion Centres in this country hold stocks of dried human fibrinogen available for immediate use, treatment need not be long delayed The prognosis is usually good, but sometimes, especially with amniotic-fluid embolism, the patient dies despite the administration of fibrinogen Awareness of the possible diagnosis and prompt treatment can, it is clear, eliminate almost completely this cause of maternal mortality

Impetigo

In the past, impetigo has been attributed to infection with either *Staphylococcus aureus*, *Streptococcus pyogenes*, neither, or both **Hope Simpson**,[1] in 1941, argued that impetigo was a specific infection which "bred true" it was not contracted from patients with boils, nor did it give rise in contacts to pyogenic lesions of other kinds Such a specific superficial reaction of the skin must therefore be due to an organism with peculiar properties and for this he proposed the name "impetigococcus" The specificity of the responsible organism was also suggested by **Spittlehouse**,[2] who reported a small series in which he had carried out phage typing of staphylococci derived from impetigo and sycosis barbæ In the former he found 81% of phage-type 71, but only 14% were of this type in the sycosis group Moreover, the majority of impetigo organisms were penicillin-resistant

These findings have been abundantly confirmed in two larger studies **Barrow** [3] found type-71 staphylococci in 80% of strains recovered from impetigo, contrasting with about 6% of this type in strains derived from a large control group Penicillin resistance in vitro was demonstrated in 71% of staphylococci from impetigo, and of the resistant organisms 84% were type 71 The results of **Parker** et al [4] are closely similar Of *Staph aureus* strains derived from impetigo, three quarters were of type 71 and most of them were penicillin-resistant

It seems unlikely that the high incidence of type-71 staphylococci in all three reports is due to a purely local distribution of the organism, for the areas concerned are reasonably far apart—Sheffield, Bradford, and Manchester **Parker** et al also examined cultures from impetigo lesions supplied by various Public Health Laboratories in widely separated areas and found that type-71 staphylococci were common *in all* The suspicion naturally arose that since many of the organisms were penicillin-resistant, they might have been hospital bred under the penicillin parasol This seems to be disproved, however, by the fact that most penicillin-resistant staphylococci are of phage types other than type 71 (In fact type 71 organisms were rarely recovered by **Parker** and his colleagues from superficial skin infections other than impetigo and they were absent in deep infections such as boils) Moreover, **Parker** et al also report an investigation carried out in Cambridge in 1941 before phage typing was adopted In this study, it was found that staphylococci derived from impetigo in young Servicemen had the property of inhibiting the growth of corynebacteria in 47% of cases (This property was present in only 19% of staphylococci derived from other skin lesions and in 10% of those from nose and throat swabs) Repeating these studies in the recent investigation they found that 90% of type 71 staphylococci and *very few others* had this property of inhibition This led to the tantalising supposition that the organisms studied in 1941 before penicillin came into use were probably also penicillin-resistant

Barrow doubts whether the presence of staphylococci in the nose is of the same significance in impetigo as it appears to be in deeper pyogenic infections (**Valentine** and **Hall-Smith**,[5] for example, reported up to 80% nasal carriage in furunculosis and as high as 91% in sycosis barbæ) In **Barrow**'s series, 46% of cases of impetigo carried the same staphylococcal type in the nose and in the skin lesions, but in his control groups a similar rate *of nasal carriage of staphylococci* was discovered He feels that if nasal carriage were important in the origin of impetigo, the rate would be much higher, Moreover, his cases of impetigo did not recur or relapse although no nasal treatment was given

These recent papers also consider the role of streptococci in impetigo **Barrow** cultured *Staph aureus* alone in 81% of lesions, *Strep pyogenes* alone in 5 6%, and a mixed growth in 13 2% He considers that in a third of the patients yielding the streptococcus it was probably the primary cause and that it was a secondary invader in the remainder **Parker** et al report that of the streptococci recovered from their patients, three quarters were of one of two closely related serological types, *one of* which was rarely found in other situations

These findings therefore support the conclusion *that* impetigo is a fairly distinct infection and that it is not an opportunist invasion by arbitrary organisms which happen to reside normally on the skin **Barrow** says that "there seems to be good clinical, epidemiological and bacteriological evidence in favour of the existence of two forms of impetigo, caused by staphylococci and streptococci respectively" It is interesting to note however, that "no clinical distinction was observed between those lesions yielding pure staphylococci and *those yielding pure streptococci*," and it is clear that, as **Parker** and his colleagues say, there is further need for correlation of clinical and bacteriological findings in this disease

Patent Ductus Arteriosus

The diagnosis of patent ductus arteriosus is seldom difficult in a typical case with a continuous machinery murmur in the pulmonary *area* With shunts of any size from aorta to pulmonary artery, there will be in addition *a* collapsing pulse, distension and pulsation of the pulmonary artery and its branches, and perhaps left ventricu points to stasis as the cause of gastric ulceration in both Why recurrent gastric ulceration after a Billroth I operation for a gastric ulcer is rare, is uncertain It could be that the less radical resection and easier anastomosis carry less risk of stenosis , more probably, there is some essential difference in gastric physiology in gastric and duodenal ulcers

Whether the high incidence of gastric ulceration is going to prove universal or is due, in this series, to some variation in technique producing stasis, only further follow up series will show Meanwhile, these results demonstrate that recurrent gastric ulcers should be treated, not by vagotomy, but by alteration of the anastomosis to a Polya type and that the combination of a vagotomy with Billroth I gastrectomy is unlikely to be satisfactory —B V McEVEDY, F R C S (University College Hospital, London, W C 1)

Vaccinia versus Poliomyelitis —I read with great interest Dr MacIver's article (Feb 4) In the United States vaccination against smallpox is required before a child may enter a school supported by State funds This usually occurs by the age of 6 7 and has not, as far as can be discovered, had any moderating effect on the reported cases In fact the Polio Foundation has regarded this as the most susceptible group The first trial of Salk vaccine was on children in the first and second grades —Colonel CHARLES H MORHOUSE, M D (Third Air Force, Ruislip, Middlesex)

The Future of the Chest Service—Your annotation of Feb 11, entitled Tuberculosis Then and Now, makes some far reaching suggestions with regard to the chest service in this country without producing evidence to give them weight and substance The degree of misapprehension of the present position it exhibits is considerable and could lead to much undesirable friction between chest physicians and clinicians in general hospitals , as future considerations will demand their closer collaboration, the whole situation requires to be examined most carefully

Prior to 1948, the tuberculosis services in this country were the responsibility of the local authorities , some were good, others indifferent in many districts radiological facilities were limited, diagnosis was thereby delayed and treatment suffered severe limitations because of the stage at which the disease was discovered and the stringency of the thoracic surgical services available The National Health Service has done much to remedy these deficiencies, particularly in backward areas, and the introduction of effective chemotherapeutic agents has contributed to an unprecedented fall in the death rate , so much so that there is a tendency in some responsible quarters to assume that this break through is equivalent to final victory You, Sir, have previously drawn attention (*Lancet*, Oct 22, 1955, p 857) to the prematurity of this assumption and to the need for strengthening the emphasis on prevention (*Lancet*, Nov 26, 1955, p 1125) But to appreciate the situation fully, attention must be accorded to the chest clinic service

The key position of the chest clinic in present circumstances has arisen simply and naturally from the resources which modern technology has placed at its disposal , in addition to ordinary large film radiography, the miniature camera has brought about in some clinics a fourfold increase in the number of persons sent for X-ray examination by general practitioners, and many of the abnormalities detected by mass radiography are referred to the clinic physician for investigation and treatment While still fulfilling his considerable responsibilities with regard to tuberculosis, the clinic physician, as a direct result of modern advances in equipment, now finds himself overwhelmed with cases of non-tuberculous respiratory ailments of every conceivable kind for which treatment facilities are inadequate and preventive measures rudimentary The training in environmental medicine which tuberculosis has given him prompts him to do his best for these patients—of all ages—who come to him with non tuberculous lung disease, many of whom present sociomedical problems similar to those met with in tuberculosis and to deal with which the chest clinic possesses the appropriate organisational nucleus in the form of health visitors and social workers

But present circumstances often preclude the chest physician from undertaking more than a fraction of what requires to be done , and pleas to his administrators are too often countered with the argument that as tuberculosis is declining and economy a prime consideration, demands for additional staff would appear to be ridiculous But it is no economy to have men who should be engaged in industry on sick benefit for months on end or to allow a child to develop into a chronic bronchitic or bronchiectatic

The unpalatable truth is that the people of this country suffer more from chronic respiratory disease than those of any other country in the world, that present arrangements for dealing with the situation are insufficient and lack coördination, and that we have barely begun to think about the problem of prevention The decline in tuberculosis has helped to unmask this long existent menace to the national health, which now faces us in the grisly reality of 30,000 deaths per annum from " bronchitis " (nearly four times the mortality from tuberculosis), over 16,000 deaths from bronchial carcinoma (more than twice that of tuberculosis), an increase in deaths from certified pneumoconiosis in miners from 232 in 1940 to 1016 in 1953 (McLaughlin, A I G *J R Inst publ Hlth*, 1955, 18, 218 (see table III, p 227)), and an untold morbidity amongst the childhood population which will seriously affect their health in later years

The problem is far from insoluble but it is apparent that if the massive subject of chronic respiratory illness in this country is to be seriously tackled a considerable reorientation of outlook is required Early consideration could well be given to increasing—even doubling—the number of consultant appointments in chest disease in industrial areas, where the morbidity from tuberculosis remains high and the incidence of other respiratory diseases is significantly greater than elsewhere , not only would this relieve the present situation in a field which has an excessive proportion of S H M O appointments, but it would encourage young men to enter a broadened specialty where indeed their services will be required for many years to come

Finally, there is a great need for closer cooperation between the medical specialists dealing with the different aspects of respiratory illness Besides physicians in chest clinics, and physicians and surgeons in chest hospitals, there is much that can be done by general physicians, pædiatricians, geriatricians, ear, nose, and throat specialists, respiratory physiologists, physical medicine experts, industrial medical officers, medical officers of health, statisticians, and general practitioners The help of all these—and more will emerge—is required to deal adequately with the problem of chest illness as it exists in this country today , and the integration of the various specialties to provide a fully functional chest service is clearly an administrative problem of the first importance Such a service should include all who have something to contribute, and existing barriers to coöperation should be removed —NORMAN MACDONALD, F R C P E (Clare Hall Hospital, South Mimms, Barnet)

Mass Radiography —On Feb 11 you reported Prof A P Thomson as saying that " among the patients in the Birmingham area examined by mass radiography in 1954, tuberculosis was found nearly seven times more frequently in those referred by general practitioners than in those in all the other groups This suggested that doctors did not neglect to examine their patients before referring them for radiography " May I point out that mass radiography is radiography without a prior medical examination—not an aid to clinical medicine, but a substitute for it The practitioners were not in fact using mass radiography at all , they were using the unit in the way I suggested when the mass radiography scheme was found to be unsatisfactory, as I had predicted (*Postgrad med J* 1944, 20, 135 , *Med Wld*, March 31 1944) The 31,249 patients sent by practitioners were examined and then referred for radiography to confirm the clinical findings The practitioners use the mass radiography unit because they cannot, as in private, refer cases direct to the radiologist but must send them to an intermediary physician or surgeon at a hospital, who alone has the right to refer them to the X ray department

Of the 364,033 other persons, examined by radiography, no fewer than 3371 (I quote from Dr McDowell's report in *Tubercle*, 1955, 36, 122) came forward individually–because they had symptoms or feared infection from contact–instead of reporting to a general practitioner Why then have any physicians at all ? Surely, as dean of the medical faculty, Professor Thomson does not consider this sound medical practice ? Of all the objections to mass radiography, the most serious is that it leads to students being taught that active progressive tuberculosis can be present without signs or symptoms It has led to neglect of the clinical examination At an inquest in this area it was reported that a patient who had repeatedly complained of his chest received no treatment , he died on the

DECORTICATION IN PULMONARY TUBERCULOSIS

DECORTICATION of the lung has proved less successful in pulmonary tuberculosis than in traumatic hæmothorax. In tuberculosis involvement of the underlying lung gives rise to difficulty in removing the "peel," and thus to subsequent air-leaks which may prevent expansion of the lung; failure may also result from hæmorrhage or infection.[1] Yet as experience grows, the results are becoming more encouraging. Thus Savage and Fleming[2] report from Sully Hospital that the majority of their tuberculous patients who underwent decortication of the lung showed significant functional improvement. In each of 34 cases where a persistent pleural space, infected or uninfected, was present, this was obliterated without inducing mediastinal shift; indeed where mediastinal shift was present preoperatively, it was at least partly reduced by the operation. In only 2 instances was thoracoplasty required to aid obliteration; but in 3 other instances thoracoplasty was carried out to control disease in the lung after the space had been obliterated by decortication. One woman, aged 47, in whom thickened pleura had been present for twenty years, and who had shortness of breath on the slightest exertion and severe œdema of the ankles, was able to continue her life as a school teacher with much improved exercise tolerance as a result of freeing her constricted left lung and restoring her displaced mediastinum to a more central position.

Such spectacular results are exceptional. Nevertheless, of 24 patients who complained of shortness of breath on mild to moderate exertion, all showed some improvement in effort tolerance after operation. No doubt in some instances this was partly psychogenic, but respiratory function studies indicated improvement, ranging from moderate to striking, in all except 2 of the 25 cases investigated. In the early period after decortication pulmonary angiograms demonstrated a poor flow through the branches of the pulmonary artery; later this flow improved with corresponding increase in oxygen uptake. Patton et al.,[3] who studied lung function in a series of patients up to three years after decortication, also found steady improvement; the final result was not closely related to the duration of the condition before operation, but where parenchymal disease is extensive, little improvement in function can be expected.

Where the extent of parenchymal disease is slight and the remainder of the lung is healthy, Savage and Fleming confidently expect a good result, provided due attention is paid to management. Preoperatively chemotherapy and physiotherapy are important, and great care is necessary during the operation to avoid damaging the thoracic duct and the vagus and phrenic nerves. Mistakes in postoperative management can nullify the best efforts of the surgeon, and it is in this respect that the Sully contribution is chiefly helpful. Savage and Fleming suggest that, if disease is not widely scattered through the lung, its failure to expand after decortication is due to inability to deal with the air-leaks and the fluid which collects in the pleural space in the early postoperative days. The lung should be fully expanded at the earliest possible moment and kept so until all air leaks have ceased. Continuous suction is applied to the drainage tubes through water seal bottles as soon as the patient returns to the ward, and the tubes are not removed till they have ceased functioning. The patient is nursed on the unoperated side, and on the second or third day is put into a special hyperextension plaster which has been made for him preoperatively; in this position the mediastinum tends to fall to the opposite side, the diaphragm is carried caudally, and the ribs are stretched apart—the reverse of the situation before operation. The patient continues to lie in the plaster cast, except for meals, for three to six weeks until chest expansion is equal on both sides or has reached its maximum; thereafter it is used for sleeping until three to six months have elapsed. Breathing exercises are begun on the first postoperative day and are continued for six months; all postoperative care is guided by frequent radiographs taken, with portable apparatus, at least twelve hourly in the early stages.

There were no deaths in the series, and the few complications were not serious; tension pneumothorax and extensive surgical emphysema were not met with, having been prevented by multiple drainage tubes with suction. The results, indeed, are encouraging enough for Savage and Fleming to state: "There is no doubt that functional improvement of significant degree can be achieved in most cases, and we are prepared to recommend operation on that ground alone." Postoperative care is the keynote to success. The management of thoracic surgical patients demands a high level of training and team-work, which nowadays, owing to shortage of skilled personnel, is not easily maintained. Attention to this vital factor is urgently required at many chest hospitals if they are to continue to meet their obligations as competently as they would like.

DIURESIS AND DIURETICS

AT the Royal Society of Medicine on Feb. 28, Dr D. A. K. Black defined the fundamental differences between water diuresis, in which solute excretion is slightly if at all increased, and osmotic diuresis, in which urinary solute is always increased. In diuretic therapy it is essential to enhance the output of sodium, and therefore all effective diuretics must cause osmotic diuresis. Diuretics can be used with advantage in states where oliguria and œdema are combined. Dr T. Hanley said that he has found acetazolamide ('Diamox') inferior to mercurials; its efficacy diminishes with continued use, owing to reduction of plasma-bicarbonate and acidosis. Dr M. D. Milne agreed with this view, and reviewed means of augmenting the effectiveness of mercurial diuretics. He recommended measures to increase plasma chloride (e.g., ammonium and potassium chloride by mouth, ion exchange resins in the ammonium cycle, or acetazolamide itself) and to increase the glomerular filtration rate (e.g., intravenous aminophylline given about two to three hours after injection of the mercurial). Cases have recently been reported in which a nephrotic syndrome has developed during prolonged therapy with mercurials. It is difficult to be certain that the renal damage is actually due to mercurial toxicity, but therapy should certainly be discontinued if proteinuria steadily increases.

CANCER AND THE PUBLIC

INSTRUCTION of the public about cancer has no stronger advocate or exponent than Mr Malcolm Donaldson, who believes that suitable explanation allays more apprehension than it causes[1] and is likely to bring patients to their doctor at an earlier and more curable stage of their disease. The effect of "cancer education" on the time of diagnosis of "accessible" cancers—i.e., those usually causing symptoms fairly early in their course—is examined in his report on a survey he made in 1954-55 on behalf of the Yorkshire Council of the British Empire Cancer Campaign.[2]

In an area comprising York, Hull, and the East Riding with a population of about 600,000, 210 lectures on cancer were given to the lay public during two years. At the end of most of these lectures ballot papers were distributed asking the audiences whether the lectures had relieved their anxiety or increased it, and whether they thought more should be given. Of more than 6000 votes 99% were in favour and only 0.2% against. In addition, more than 50,000 pamphlets were distributed, articles were published in the press, posters advertising the campaign were displayed, and diagrams explaining cancer and its treatment were shown in local health exhibitions. Nurses, health visitors, and midwives were given special lectures to enable them to discuss cancer with patients. The value of these measures appeared most convincing in cancer of the rectum, where the proportion of patients reporting symptoms with less than a month's delay rose from 16.9% to 33.7% and 43.8% during successive six-monthly periods. There was a slight rise in the equivalent figures for cancer of the breast, which were 35%, 37.7%, and 39%; but those for the uterus showed no material improvement—partly because patients found it hard to distinguish physiological from pathological bleeding. There were so few cases of cancer of the larynx, mouth, tongue, and bladder that the results were inconclusive, and in cancers of the skin early diagnosis is relatively unimportant.

As Donaldson says, this Yorkshire experiment, and the Manchester survey[3], "should prove to be of real value to any other local health authorities who are proposing to carry out cancer education of the public, which is so stongly advocated by the Ministry of Health." The results of the two pilot

Notes and News

On Feb 1 the Joint Consultants Committee considered a document embodying the Ministry of Health's proposals on the medical staffing of hospitals (This was the Ministry's reply to the proposals—based broadly on the Strachan report—which the committee submitted last July) After a general discussion it was referred to a subcommittee for detailed examination Pending any changes in the structure of hospital medical staffing the Ministry is being asked to continue the present transitional arrangements to safeguard the position of senior registrars

The epidemic of influenza in Suffolk (see *Lancet*, Jan 28 p 200) was largely due to virus A *Of the specimens sent for examination*, the great majority showed a high titre of A antibodies There has been a considerable increase in mild influenza like illness in many parts of the country Outbreaks are reported from places as far apart as Bristol Guisborough, West Hartlepool, Great Yarmouth, Dover, and Hastings

The net cost of the National Health Service in England, Wales and Scotland in 1956–57 is estimated at £502,715 130 The cost in 1955–56, with the supplementary estimate, is put at £479,337,405 In the coming financial year the social services are to receive altogether an additional £99 million including an increase of £32 million *for the* education services (1956–57 Vote on Account Civil Estimates *H M Stationery Office 6d*)

On Feb 11 the degree of M B of the University of Cambridge was conferred on Rosemary C Hayball, and (by proxy) *on* Mary R Glyn-John

Dr E Stengel has been appointed professor of psychiatry in the University of Sheffield

Dr Andrew Curran deputy medical officer of health for West Ham has been appointed senior lecturer in public health and social medicine in the University of Glasgow

On Feb 11, the Charter Day of the Royal College of Surgeons in Ireland the honorary fellowship was conferred on Dr R B Cattell and Sir Clement Price Thomas

A Chadwick Trust prize of £100 together with a silver medal, has been awarded to Group Captain Christopher Crowley for his contribution "in organising and administering measures for promoting health in the R.A F Maintenance Command "

At the annual dinner of the Hunterian Society on Feb 16 the Lord Mayor of London Alderman Cuthbert L Ackroyd replied to the toast of the Lord Mayor and Corporation, proposed by Dr J Y Dent The toast of The Society was proposed by Sir John Maud and the president Mr A Dickson Wright, responded Sir Heneage Ogilvie welcomed the guests for whom Mr Douglas Fairbanks replied

The trustees of the Lady Tata Memorial Fund invite applications for grants scholarships, or fellowships for research on blood diseases, with special reference to leukæmia in the academic year beginning next October Programmes of research on any aspect of malignant disease which may throw light on problems of leukæmia will be considered and awards may be made to investigators of any nationality, working in any country where payment can be made Particulars and application forms may be had from the secretary of the (European) Scientific Advisory Committee Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road London S W 3 Applications must be submitted before March 31

The proceedings of the Fifth International Congress of Blood Tranfusion held in 1954 have been published in Paris The 1200 pages cover the four sections—immunohæmatology clinical problems, preparation and preservation of blood and its constituents and organisation The book is obtainable for 5000 francs from the secretary-general of the congress 58, Boulevard d Auteuil, Bologne sur Seine France

The following doctors have been appointed to the Scottish Health Services Council Dr J C Macarthur, Prof W A Mackay, Prof W M Millar, Dr Eric G Oastler, and Dr I B L Weir Dr C W Clayson and Prof J L Henderson have been reappointed

The first publication of the College of General Practitioners to be offered for sale to the medical profession is a report of their conference on general practitioner obstetrics held last November Copies (3s 6d) may be had from the college, 14, Black Friars Lane, London, E C 4

Four countries—Cambodia, Laos, Thailand and Vietnam—have decided to merge their malaria control programmes in an effort to rid the Indo Chinese peninsula of this disease

Air Commodore A F Cook has been appointed an honorary physician to the Queen in succession to Air Vice Marshal R H Stanbridge who has retired from the R.A.F

A Food Standards Committee *report on copper (H M* Stationery Office, 6d) recommends limits for the copper content of soft drink concentrates, certain non alcoholic beverages, yeast and yeast products, and solid pectin The report does not advise giving statutory effect to these limits as has been done for the limits recommended *for edible gelatin and tomato ketchup*

The report of the Marie Curie Memorial Foundation for 1954–55 records an increase in annual income from £85,000 to £116 000 The Foundation hopes presently to open a fifth home to serve the north-eastern counties

The British Council for Rehabilitation in conjunction with Queen's University Belfast, is holding in Belfast from March 21 to 23 a residential conference on the Development of Rehabilitation Services in Northern Ireland A public meeting will be held at the City Hall on March 20 and there will be an exhibition of aids for the disabled in daily life The council s address is Tavistock House (South), Tavistock Square, London, W C 1

To try to keep together at home families where children might otherwise have to be received into care the health committee of the London County Council propose to employ some 50 additional whole-time home helps The committee also propose to provide selected home helps to work with and teach housecraft to mothers who need help of this kind Five days training will be given in the first instance to some 85 home helps who will work in families under the guidance of health visitors Basic kitchen equipment will be lent to families when necessary

The first issue has appeared of the *German Medical Journal*, a monthly English language edition of the *Deutsche medizinische Wochenschrift* This edition edited by G R Graham is obtainable from the publishers, Georg Thieme Verlag, Herdweg 63 Stuttgart, Germany for £1 10*s* per annum

We do not claim that the use of high-potency vitamins provides the whole—or even the most effective—method of treatment but we do suggest that the striking clinical results which we have observed can be accounted for in terms of known enzyme chemistry

The interest shown by clinical psychiatrists in this field should not come as a matter of surprise, in view not only of the rapidly increasing use of barbiturates in attemped suicide but also of the interesting psychiatric syndromes resulting from the use of barbiturates as sedative drugs during the day and hypnotics at night over long periods In my department these syndromes—often unrecognised—have come to be known unofficialy as "chronic subclinical barbiturate intoxication"

These considerations make the continued collaboration of clinicians and biochemists a matter of urgency to meet what may without exaggeration be regarded as a social menace —E B STRAUSS, F R C P (St Bartholomew's Hospital, London E C 1)

Tuberculosis and Liver biopsy —Dr Engstedt suggests (Feb 25) bone marrow aspiration in cases of tuberculosis In 1952 Mr *Barton and I reported on examination of rib* bone marrow in patients undergoing surgical treatment (*Lancet*, 1952, ii, 1059) We were unable to demonstrate tubercle bacilli either by smear or culture We suggested that the ribs removed in thoracic operations could be used in orthopædic units for grafting But subsequently Dr Lack pointed out that he knew of two cases of tuberculosis which had occurred when ribs from tuberculous patients had been used for spinal fusion for scoliosis (*Lancet*, 1952, ii 1182) He suggested that if the aspirated bone marrow had been placed in a muscle pouch of the guineapig our results might have been different, but we have had no opportunity to carry out this work —KENNETH MARSH, D M (Chest Clinic, Camberwell, London, S E 5)

The Future of the Chest Service —Dr Macdonald (Feb 25) has pointed the right way for the future

Despite the moans about "splitting" of the old tuberculosis service, the chest services have have been one of the successes of the National Health Service Thanks to improved diagnostic and therapeutic facilities, pulmonary tuberculosis is being brought under control It is, however, far too little recognised that many clinics and sanatoria have been doing increasing amounts of non-tuberculosis chest work and penetrating an unexplored field of chronic invalidism Much of this invalidism is preventable, and, as Dr Macdonald says, the sociomedical problems of, say, chronic bronchitis are strikingly similar to those of the patient with tuberculosis

The chest services, with their staffs of physicians, health visitors, and almoners, and using the welfare facilities of the local authorities through the medical officers of health, are in an exellent position to launch an all out attack on chronic respiratory disease The indications are for expansion, not contraction, and for progressive integration with the general hospital services Initial expenditure would not be high and dividends would very soon come in —GWYN HOWELLS, M R C P (Littleover, Derby)

Gluten to Blame?—Your annotation (Feb 25) suggests that at the Royal Society of Medicine I attributed the "precœliac syndrome" to agene In fact I was as careful to avoid such a specific imputation as I was in my letter of Feb 18 *Observations on my cases suggest* that the "staling" *process* of flour may be connected with the cause of this syndrome Flour may become stale through being kept too long, or it may attain similar properties as the result of treatment by the various "improving" processes to which it is usually subjected

In the past three years at a residential nursery school here I have seen no case of the precœliac syndrome, notwithstanding a number of epidemics including measles The reason may be that the bread, biscuits, and cakes included in the children's diet are made only from fresh untreated stone ground flour

Recent research has shown that when flour becomes stale there is a progressive loss of its vitamin E content, and this vitamin is quickly and completely destroyed when the flour is treated by agene or chlorine dioxide This might suggest that a vitamin E antimetabolite plays a part in the ætiology of the precœliac syndrome

The patient to patient *variation in the manifestations* of cœliac disease was brought forward as an argument against the connection between this disease and the syndrome I have described There is considerable variation from patient to patient also in the precœliac syndrome when symptons have been present for two months or more, it is only in the early weeks that the signs are so consistent

Your annotation suggests that there is little resemblance between canine hysteria and cœliac disease Veterinary workers recognise that canine hysteria can occur when a dog eats no agenised bread, thus methionine sulphoximine is not the only cause of this condition in dogs, and I have never suggested that it was the only cause of the precœliac syndrome Canine hysteria due to causes other than agene, after having been present for a few months, resembles cœliac disease quite closely, apart from the fits The dogs lose weight, have distended abdomens, have poor appetites, are bad tempered and unfriendly, and may have pale, bulky, foul smelling stools Also as in cœliac disease, these symptoms are greatly aggravated by infections

Clearly much further research is needed to elucidate the cause of this syndrome, whatever this may prove to be, at least we have in the gluten free diet a valuable symptomatic treatment to speed convalescence after infections, which will be appreciated by both *patients and parents* —GUY DAYNES, M R C S (Hove, Sussex)

***Production of Codeine*—*I agree with Dr Williams* (Jan** 21) that the amount of codeine in tab codein co does not enhance the analgesic value It does, however, produce side-effects, in particular constipation, which limits its continued use in such common conditions as the chronic rheumatic diseases

Recently I have compared the effect of a new analgesic *n* acetyl *p* aminophenol ('Panadol,' Bayer Products) with tab codein co in 20 cases of chronic rheumatic disease found in my general practice Side effects developed in 12 cases on tab codein co, but in only 1 on panadol It appears that this new drug has an analgesic value equal to that of tab codein co with the advantage of having fewer side effects

In my opinion the only effect of stopping the production of codeine would be, as Dr Williams implies, to reduce the consumption of laxatives —R R HAMILTON M B (Hawick Roxburghshire)

Prevention of Hay-fever —At this time of year, when hay fever sufferers are beginning some form of prophylactic treatment, my experience with a patient who has had hay fever for over thirty years may be of interest

Using 'Pollacine' vaccine (Parke, Davis), in fourteen doses I have advanced from 500 units to 30,000 units by administering, as an adjunct to the vaccine, chlorpromazine maleate ('Piriton Maleate', Allen & Hanburys) 10 mg in 1 ml This is added to the recommended dose of pollacine with a small amount of lignocaine to reduce the absorption and the pain from a 2 ml injection into the deltoid muscle The patient has had no untoward reaction He carries with him as a safety measure tablets of piriton, with instructions to take two (8 mg) at once if there is any delayed reaction To date this has not been necessary He is inclined to be drowsy by early afternoon, and this is overcome by his taking one tablet of 'Preludin' (Pfizer) during the morning At this rate the total course of some sixty injections, ranging from 500 to 150,000 units, can be reduced by two thirds, with a substantial saving of both doctor's and patient's time

The advantage of piriton over other anti histamine substances which have been administered to this patient is the very slight reaction —DOUGLAS STATHERS, M R C S (*Caterham,* Surrey)

New Kidneys for Old —I agree with your views as to the possible importance of kidney transplantation as an eventual therapeutic goal It would seem unfortunate, however, that you apparently remain ignorant of the work in this field carried out in this country May I draw attention to some of the errors in your leading article of Feb 18

(1) The problem of renal homotransplantation was not discussed at the Ciba symposim in 1954 (Preservation and Transplantation of normal tissues London, 1954)

(2) Your reference for the evidence of common antigenicity of skin and kidney cites a paper (R E Billingham et al *Ann N Y Acad Sci* 1955, 59, 409) which does not consider this problem let alone give any evidence The two relevant publications are as follows M Simonsen, F Sorensen, *Acta chir scand 1949, 99, 61* W J *Dempster, Brit J plast Surg* 1953 5, 228

Printing of The Lancet

Outside London, normal printing has been resumed pending the decisions of the Industrial Courts But in London the printing houses remain paralysed, and several periodicals have ceased to appear in any form We trust that an early settlement may enable us to make up for some of the deficiencies of our current issues

B C G

A report by the Medical Research Council published last week[1] confirms that vaccination with B C G or vole-bacillus vaccine can prevent the clinical manifestations of tuberculous infection particularly miliary tuberculosis and meningitis The investigation, which involved 56,700 fourteen-year old children living in English cities and towns, was well planned, carefully executed, and clearly reported the results are unequivocal It is estimated that a general vaccination scheme of children of this age should reduce tuberculous morbidity between the ages of fourteen and seventeen by about half and the more serious types of disease might be reduced even more, for in the M R C investigation meningitis or miliary tuberculosis developed in none of the vaccinated children but in 6 of the unvaccinated

This investigation will provide valuable information and encouragement to those concerned with the public health, both in this country and (which is more important) in the less highly developed countries where vaccination is the only effective measure that can at present be applied Yet, as the report points out, "although it is now more than thirty years since B C G vaccine was first used in man" this "is the first controlled trial of the vaccine to be undertaken in Great Britain," and many of us will long regret that we did not press for such a trial sooner When it was eventually undertaken in 1950, B C G had already been in use in many countries since its introduction in France twenty six years previously[2] and though much of the published evidence of its value was invalid, and justified the initial scepticism with which it was regarded, there had also been several extensive planned investigations almost all of which suggested very strongly that B C G was useful None was unassailable close critical examination showed possible sources of error in each But it now seems that too much attention was paid to the fact that bias had been introduced into these trials, and not enough attention was given to the possibility that this bias had not materially affected the results Prof **JOHN FRANCIS**, who insisted in 1949 that what was needed was not so much an adequate trial of B C G as a campaign for its use, argued that exceptionally severe criteria of efficacy were being applied, in Great Britain, to this vaccine "the evidence supporting the value of B C G," he said, was "better than the evidence supporting the value of any *other* immunological procedure used in man"[3] Certainly, it has long been better than the evidence in favour of the poliomyelitis vaccine shortly to be offered to the public

In 1949 the Ministry of Health who control the manufacture and distribution of B C G vaccine, allowed it to be used routinely in those exposed to special risks, and later they permitted vaccination of school-children not exposed to special risks—stating, however, that, in order not to interfere with the M R C trial "any extension of the present B C G vaccination scheme should not include young adolescents aged 15 to 18"[4] But, as we pointed out,[5] vaccination of children and adolescents will not prevent infants dying from tuberculous meningitis Of the children in the M R C trial 40% had already been infected by the time they were fourteen Even at thirteen—the age at which school children are now vaccinated—it is likely that at least 1 in 5 will already be infected at birth none are infected Last year we suggested that B C G vaccination should be made available to all who wanted it and that the practising doctor, who bears a more direct responsibility than public-health authorities for the health of those under his care should be free to decide whether his patients should have B C G[6] We hope that vaccination has now been offered to the unvaccinated volunteers in the M R C trial who are still uninfected

Iron Foundries

REGULATIONS which should promote health, safety, and welfare in iron and steel foundries[7] came fully into operation at the beginning of this year, and the first report[8] of the Joint Standing Committee on Conditions in Iron Foundries is timely, because it makes practical suggestions about the control of dust and fume

The founding of metal is an ancient craft—so ancient that, under the weight of tradition, both employers and workers have regarded the hot, dusty, and dangerous conditions as inevitable, and the campaign for better working conditions did not begin in this country until the late 1930s A leading article which we published at that time[9] was based partly on American experience and partly on observations by doctors in the Factory Department and the Silicosis and Asbestosis Medical Board Ever since then the Factory Department has kept up steady pressure, and during the war the Chief Inspector set up two joint advisory committees, one for steel and the other for iron foundries About the same time a survey of the health risks of iron and steel foundry workers was begun by the Factory Department in conjunction with the Medical Research Council's department for research in industrial medicine directed by Dr. **DONALD HUNTER** at the London Hospital The results of this survey,[10] of which Dr A I G **MCLAUGHLIN** was in charge, were published in 1950 In 1947 a very thorough report[11] from the Joint Advisory Committee

RESTRICTION OF ANTIBIOTICS ?

On Jan 28 we discussed the New Zealand government's decision to restrict the use of erythromycin so as to conserve its efficacy against infections resistant to all other antibiotics In considering what policy might be evolved to ensure the best use of antibiotics, we made no mention of one important interest—that of the manufacturers Some manufacturers have done their utmost to ensure wise use of the powerful drugs they introduce, and they have sometimes done the public and the profession a service also by refraining from putting a new drug on the market when the medical evidence was not entirely in its favour By maintaining high standards in these matters a firm may lose a lot of money, and full credit should be given likewise to those who do not over optimistically broaden their claims for antibiotics, or hint (with the help of quotations from medically qualified but uncritical observers) that there is scarcely an infection in which their product is not worth a trial Equally we should be grateful to firms who act with restraint when they find themselves in possession of "new" antibiotics whose claims to novelty may be slight Some of the drugs which have appeared under new names have in fact so much in common with established antibiotics that there is no real justification for bringing them forward Indeed they may do actual harm by increasing the number of organisms resistant to drugs already in use There is some evidence, for example, that this may be happening in France with a drug which closely resembles erythromycin and has no clear advantages over it Fortunately, this antibiotic has not appeared on the market in this country, for our manufacturers have wisely stayed their hand

The drug firms, perhaps, can do more than anyone else to teach doctors how best to use antibiotics, and they certainly have the information necessary to regulate the supply in such a way as to discourage the emergence of resistant organisms Such regulation, however, could involve heavy financial sacrifice, and if certain antibiotics are to be "rested" by agreement, from time to time, arrangements will have to be devised for compensating the firms thus penalised in the public interest

VENOUS ULCERS

It is custom to label as "venous" those ulcers which persist or recur above the inner malleolus and which are surrounded by pigmented and atrophic skin Often a cause for the ulceration is readily found—for example, a previous "white leg" or grossly incompetent varicose veins But sometimes the cause is uncertain or is presumed to be a silent phlebitis or venous incompetence due to deficient valves

Why these ulcers develop almost exclusively around the internal malleolus has never been very convincingly explained Cockett[1] believes the venous anatomy of this region may offer a clue From his studies on cadaver dissections he describes a large constant "posterior arch" vein which winds from the internal saphenous vein down the posterior aspects of the inner calf, *superficial* to the deep fascia, to anastomose *finally* with a series of small venous arches These small arches feed into three perforating veins which pass through the deep fascia above the internal malleolus and empty directly into the posterior tibial veins Although there is some variation in his dissected specimens, the perforating veins are short and reasonably large vessels, whose valves are so arranged that blood normally flows inwards from the subcutaneous tissues through to the subfascial veins but not in the reverse direction It is thus suggested that in the erect position the major venous outflow from the ulcer bearing area is directly into the deep veins via the perforating veins and not, as holds for the rest of the skin of the leg, into the saphenous system It follows that the small vein arches may be distended via the "posterior arch" vein from an incompetent internal saphenous vein or from the deep venous system, should the valves in the perforating veins become inefficient

Cockett's thesis is that venous ulcers and associated induration of the lower leg are usually due to destruction of the valves of these ankle perforating veins, and an operation designed to interrupt them is a logical step in the treatment of these ulcers Patients should be carefully selected the older patients and those with long standing ulcers in whom the whole of the lower third of the leg is strangled in a mass of indurated fibrous tissue are excluded and treated by the well established methods of supportive bandage and massage

In the 200 "selected" patients on whom Cockett has operated, a straight incision was made one finger's breadth behind the posterior margin of the tibia from midway between the knee and ankle down to 1 in above the internal malleolus This included an excision of the ulcer and any doubtful skin Any large subcutaneous veins were dissected out and followed up and down They led to one or other of the perforating veins and most commonly the upper and middle ones were found enlarged These were then ligated flush with the deep fascia and the whole plexus of subcutaneous veins excised Any large veins which diverged from the area of the incision to join the saphenous system or other perforators were followed and removed if necessary through separate incisions Excessive undercutting of the skin was avoided since this leads to extensive skin necrosis, a complication which may take longer to heal than the original ulcer In 135 operations for ulcers unassociated with superficial varicose veins, incompetent ankle perforators were present in 96 In 54 cases in which the ulcer was associated with varicose veins, an incompetent perforating vein which contributed to the persistence of the ulcer was present in 36

In a condition where many methods of treatment have been advanced only to disappoint, Cockett is commendably cautious about his results The follow up period is still short but the early results are promising

ALCOHOLISM ON THE CONTINENT

In its second number,[1] the *International Journal on Alcohol and Alcoholism* includes two contributions which throw important light on the extent of and the reasons for the recent increase in alcoholism on the Continent

An article by Hans Seidel discusses the development of alcoholism in the German Federal Republic since the war and shows that alcohol consumption in Western Germany, especially consumption of Branntwein (the German brandy product), has once again almost reached the high figures of the immediate pre war years under the Nazi régime In the past few years in the wake of the spectacular economic recovery of the country, "a kind of forced, hothouse alcoholism has come to the fore" Seidel regards this to some extent as a consequence of the systematic drinking during the war in the Army, as well as in other National Socialist organisations Large quantities of French hard liquor were sent to the German army during the Russian winter campaigns He also mentions the accumulated demand for stimulants after post-war shortages and privations Above all, however, he explains the present "hasty, unquiet and ostentatious form of drinking" as an expression of widespread inferiority feelings arising out of the social and political upheavals following the war

Alcoholism, Seidel suggests, is closely connected with the appalling figures of road accidents in Western Germany, as high a proportion as 25% of road deaths has been attributed by some experts directly or indirectly to alcohol consumption The number of habitual alcoholics in Western Germany is placed at between 180,000 and 200,000 or something over 4 per 1000 of the population But it seems that little effort is being made to tackle the situation Modern methods of treatment are said to be little used and difficult to enforce, the number of beds in non mental hospitals is described as hopelessly inadequate for systematic treatment, and social-insurance authorities are extremely reluctant to meet the cost of lengthy treatment

Dr Gabriel Mouchot gives some of the background to recent steps by the French government to combat alcoholism,[2] and he assesses their scope and prospect of success in a rather sarcastic way "It is easy,' he declares, "to drive a coach and four through recent liquor legislation," for the law cannot do much unless backed by public opinion, and "almost everyone in France thinks that wine, or brandy, or whatever he drinks is good for him!" Alcohol producers moreover, are numerous, rich, and powerful Several million Frenchmen depend on drink for their daily bread, millions of acres are covered by vineyards In the circumstances, few politicians and certainly no government which hopes to remain in power are likely to possess the hardihood to tackle the root problem —over production "So long as we have no precise ideas," may be suppressed, and be replaced by no more than the equivalent amount of exogenous hormone In theory the only advantages to the patient would be the substitution of a regular supply of hormone for the varying output of his own glands (the maximum secretion during a twenty-four hour period may be ten times greater than the minimum) or the very hypothetical suppression of a harmful adrenocortical hormone Before adopting a policy of "safe" maintenance therapy we must try to establish whether we are, in fact, using an expensive drug to any good purpose

Clean Meat?

THE importance of meat as a source of food-poisoning, to which we lately called attention,[1] is not peculiar to this country or this age As long ago as 1880 BOLLINGER collected details of 17 outbreaks of food-poisoning due to meat and affecting 2400 people[2] In 1888 GAERTNER[3] described the organism which for so long bore his name and which we now call *Salmonella enteritidis* he recovered it from the carcass of a cow, and, post mortem, from a man who had eaten the meat The Aertrycke bacillus (now *S typhimurium*) owed its name to the Belgian village where it was first detected by DE NOBELE[4] under like circumstances Though we owe much to our own Durham and the reports of the Local Government Board, it was the German bacteriologists who paid most attention to food-poisoning in those early days One reason for this was the national habit of eating undercooked meat, and one result, a system of meat inspection which should be the envy of every country

The report of a joint committee of the Food and Agriculture Organisation and the World Health Organisation emphasises that our most valuable source of protein has its dangers[5] The list of meat-borne diseases is intimidating, though some of them—brucellosis, tuberculosis, and erysipeloid, for example—threaten the butcher rather than his customers (In some parts of the United States undulant fever has become principally an occupational disease of slaughterers[6]) Even if the problem is limited to salmonella infections alone, the difficulties in offering the housewife food free from all possible risk are very considerable In this country at any rate, bovine infection with *S typhimurium* and *S dublin* is not uncommon, and diagnosis, in life or after death, must depend upon a bacteriological examination which is seldom made Conditions in the best run abattoir are seldom such that contamination of clean meat by infected viscera or fæces is impossible Even in this enlightened land the design and practice of too many abattoirs are archaic of conditions in some of our Colonies the less said the better Nevertheless experience and the statistics of the Public Health Laboratory Service shows that "a cut off the joint" is seldom the origin of salmonella infection The commonest source is processed meat in one of its various forms A list which did not claim to be comprehensive mentioned 61 varieties cooked before sale and another 4 (including the domestic sausage) which are sold raw in this country[7] Not even the makers would claim that the meat which goes into these succulent foodstuffs is the same as that on the butcher's slab These dishes are in fact a sensible way of using up all those parts of the animals' anatomy which are in their pristine state repellant to our squeamish tastes But liver, spleen, and lymph glands can be reservoirs of bacterial infection, and an inside view of the trade will reveal other components, both native and imported, sufficiently bizarre to encourage further inquiry

If all this is true of Great Britain it is likely that the practice of hygiene is even more difficult in countries where meat is preferred when it has been ripened by decay or where a chronic shortage of protein gives every scrap of a carcass added value This report does not concern itself with the details of practice but lays down general principles which are hard to fault Two new developments are mentioned which have not had much attention here There is probably little cruelty in a well run abattoir, but the preliminary stunning of pigs with carbon dioxide points to further improvement in this direction Some process by which meat might be sterilised cheaply and without danger of taint might well remove many troubles in the meat trade Some trials of irradiation for this purpose are so promising that the subject is recommended for further study by the committee Their report is said to be the first of a series, and we look forward to its successors

Chest Radiography in Pneumoconiosis

To certify a miner as having pneumoconiosis is a grave responsibility apart from his natural dread of the disease, he and his family will inevitably suffer hardship, and the mining industry may lose a skilled worker who is badly needed According to the Ministry of National Insurance[1] the diagnosis of pneumoconiosis depends primarily on radiography, but how reliable is this?

On the results of a survey made in 1950-51 in four Durham coalmines,[2,3] Professor BROWNE and his associates now question the value of radiography in assessing pneumoconiosis Of the 5118 men examined (89% of all those working in the four coalmines) 30-35% showed radiological evidence of the disease, and for men who had worked at the coalface for twenty years or more the figure was 65% A little over 2% of all men had radiological evidence of complicated pneumoconiosis (progressive massive fibrosis) When allowance is made for Durham miners going to the coalface ten years earlier than their Welsh colleagues, these figures agree closely with those recorded by the M R C workers for four coal mines in South Wales, in the Rhondda Fach[4]

But in the Durham survey NEWELL and BROWNE[2] recognised, in uncomplicated pneumoconiosis, no association between symptoms and radiological category A man with symptoms might or might not have had an abnormal radiograph Hence they believe that "many men who have no symptoms may be classified as having radiological pneumoconiosis, while many who are disabled cannot be so classified and compensated, as there is no abnormality in their radiographs", and they point out that dyspnœa, cough, and spit, which are disabling to the patient, cannot be detected radiologically Their general conclusion is that whereas radiological category is influenced by the degree of dust exposure, the disability of coalface workers is a function of age They suggest that, if their findings are supported by those in other coalfields, the compensating machinery for miners' pneumoconiosis should be reconsidered

> "Disability (as measured by inability to continue the present job) in a coalface worker might well entitle a man to compensation Let the chest radiograph be boldly omitted At present many men are being refused compensation because their chest radiographs are normal, even though they are grossly disabled, and vice versa"

McCALLUM and BROWNE[3] hold that, in the interests of both the men and the coalmining industry, it would be

Letters to the Editor

Poliomyelitis Vaccination —Since I began to work on poliomyelitis vaccine, I have often been asked whether I would have my own children injected with the current type of vaccine In spite of the official information which has been given, there is still a surprising degree of ignorance of the basic facts about this vaccine, perhaps because its practical development has preceded the publication in this country of the scientific data necessary for its appraisal It rests therefore with those "in the know to give what reassurances they can

I hope that my children, at least those that are eligible, will receive poliomyelitis vaccine this spring I am satisfied that the vaccine can do no possible harm Since the revised safety regulations were introduced last summer, reactions and side effects have been virtually nil in over 10 million children vaccinated in the United States and elsewhere The safety margin of the vaccine has been widened enormously in the last year and in this country in three different ways (1) by using the very much larger volumes of sample for the safety tests, as introduced in the United States last summer, (2) by doing the safety tests in duplicate and independently in two different laboratories, and (3) by using attenuated strains of virus to prepare the vaccine

Much less certain is the amount of good the vaccine will do It is hoped to produce vaccine of a standard at least equivalent to that of current American production, which, to judge by the most recent figures, has a protective effect of between 70% and 80% That is to say, the risk of contracting *paralytic* poliomyelitis for a vaccinated child is about a quarter or a fifth of that for an unvaccinated child It may be argued that the risk of contracting paralytic poliomyelitis in this country is pretty small For children aged 2 5 years the chance is about 1 in 3000 in a year that is about average for poliomyelitis incidence But those who are familiar with the consequences to the individual and to the family of a crippling and fatal illness will wish to lessen that risk for their own family And thus is the advice I think doctors should be giving to their patients and friends —ALAN GOFFE, M B (Wellcome Research Laboratories, Beckenham, Kent)

Remuneration of Doctors —As a country practitioner I am rather tired of the pious horror with which some of my prosperous colleagues greet our proposals for an increase of pay Let us be realistic We are not taking the first plunge into an antisocial debauch of inflation Instead, we are bringing up the rear in a rather sorry race, which we did not want to start Does Professor Davis (Feb 18) really believe that our example, at this late stage, will influence electricians, teachers, or railwaymen one way or the other ? It seems to me that the true position of our high minded critics is revealed by a sentence in the last paragraph of Professor Davis s letter "instead of pressing salary claims obtaining a modification of the present taxation system " I should like to ask which of the two measures would more accelerate inflation—increase of doctors' remuneration, or a general relaxation of taxes for higher income groups ?—M A FENTON B M (Moreton in Marsh, Gloucestershire)

We should like to support the opinion, expressed by the Royal College of Physicians of Edinburgh (Feb 18, p 296), that no claim for increased remuneration be submitted at present We feel that it is the duty of the medical profession, as a responsible section of the community, to give a lead which, we hope, others may follow —E G HALL, M B , F P HUDSON, F.R C.P.E , A E MCCANDLESS, M.R C P , R M.TODD, M.R C.P (Alder Hey Children's Hospital, Liverpool)

I should like to add my voice to that of those who consider the present time inappropriate for claiming increased remuneration —R.D REID, M B (West Mersea, Essex)

Factory in a Hospital —I would agree with Dr Rollin and Dr Watkin (Feb 18) if I had claimed that the factory had cured any of our patients, or that it would, by itself, lead to the discharge of any number I made no such claim My intention was to provoke discussion of the issues which the factory project, with other social changes, raises Many of our long stay patients are harmless, and if they can be trained to be self supporting it would seem unnecessary for them to remain in hospital Changes in the law and the recent introduction of non statutory beds together with the open-door ' policy, have helped to show the public that the psychotic patient rarely needs isolation because of dangerous behaviour If we can show that even the deteriorated patient can be useful to the community, yet another source of prejudice will be removed

Most psychiatrists working in mental hospitals complain of the overcrowding, and this has led to a damand for new building and more hospitals Schizophrenia is a chronic illness with frequent relapses, but so are peptic ulcer, bronchitis, and rheumatoid arthritis If patients with these diseases were kept in hospital for fear of relapses and because of the risk of "accidents if they left, the general hospital, too, would soon be overcrowded

More patients will leave the mental hospital only if there is a change in the attitude of society so that room is made for them in the community Our factory may help to stimulate such a change—A A BAKER, M D (Banstead Hospital, Sutton, Surrey)

Too Much Barbiturate ?—We also have encountered some of the complications mentioned by Miss Brooke (Jan 21), such as chronic barbiturate intoxication, barbiturate addiction, and severe withdrawal manifestations, including grand mal seizures and a picture closely resembling delirium tremens We have in the last few years investigated new types of hypnotic sedative drugs unrelated to the barbiturates These included methylpentynol, α phenyl α ethyl glutarimide, 2, 4 dioxo 3, 3 diethyl methyl piperidine and 1 ethinylcyclohexyl carbamate So far we have found these drugs quite satisfactory, although the observation period is obviously much too short to make any definite claims Exercise of restraint in the prescription of any hypnotic is obviously the most satisfactory solution , but it is important that the use of these new compounds has enabled us to dispense with barbiturates (for insomnia) altogether in the ward concerned for the past eighteen months —M M GLATT, M D (Warlingham Park Hospital, Warlingham, Surrey)

Protophrenia—Dr Bourne's letter (Feb 4) is an astonishing mixture of misquotations and fantastic distortions of statements I made in earlier letters According to him, I said that ' only feckless parents would seek hospital care for an imbecile child if he looks anatomically normal " What I really said was " few parents of a normal looking child below school age who can walk and can control his sphincters will agree to have him certified as a mental defective " I concluded that this circumstance " may explain why almost all Dr Bourne's residual ' cases have feckless or otherwise unsuitable parents " Not I, but Dr Bourne, showed that almost all his ' residual " cases had " feckless or otherwise unsuitable parents " He continues " *Plainly from this, she knows nothing of the burden such a misfortune may bring to a working class home* " I have in fact first hand knowledge of the burden such a misfortune may bring to people who have to work for their living , I have also discussed this problem with many parents from the Association for Mentally Retarded Children in the U S A and from the Society for Mentally Handicapped Children (S M H C) in England—many of them ' working-class "—who, like me, steadfastly declined to apply for institutional care for their pre school age children Regarding Dr Bourne's refutation of my second " extravagant ' assertion—that his proportion of residual cases was unduly small—I can only advise him to visit a few outside children's parties arranged by groups of parents in the S.M.H C He will then see that a high proportion of the under-fives (or sixes) look completely normal His question " which outpatients ? " is thus easily answered

Dr *Bourne* says that my theories directly contradict my previous statement Why ? Because I stated that these children look normal but that most of them reveal to the expert signs of neurological disturbances ? I did not say " all," as Dr Bourne asserts He goes on to say that my clinical signs of organic disease " are only to be found by the esoteric methods of neurological examination prescribed in her unpublished papers " I described several of these well-known signs in my letter and referred to others published in two English journals accessible to everybody Finally Dr Bourne declares that he has read my other letters to the medical press But when reading his comments I started wondering how he could possibly have read them Where did he take it from that " A single child's case was enough to convince her that defect arises not from inadequacy of the rest, its position did not alter on deep inspiration followed by the Valsalva manœuvre, whereas in patients with lung hernia this caused the apex to bulge upwards. Although some of Fenichel and Epstein's patients were alarmed at the appearance of supraclavicular swelling, they suffered no inconvenience and, as is usually the case, no treatment was necessary. Exceptionally, however, the condition has given rise to severe pain,[10] and Rigden[11] described a patient in whom surgical repair of an intermittent cervical hernia had to be undertaken partly because of local discomfort, but mainly because protrusion of the lung was accompanied by throbbing in the head and neck.

MORBIDITY AFTER PROSTATECTOMY

Since surgical treatment was first used for benign enlargement of the prostate, it has undergone many modifications. The primary aim has always been to ensure permanent relief from the threatened dangers of urinary obstruction and to do so by an operation of low mortality. This objective can now be attained by suitable selection of cases and careful attention to technique, and the problem of reducing postoperative discomfort and morbidity now commands greater attention. In a symposium on morbidity following prostatectomy held in Melbourne last year, a number of leading Australian urologists recorded their experience with particular operations. Basically all agreed on the need for complete removal of obstructing tissue, the control of hæmorrhage, and avoidance of infection; and when these conditions had been fulfilled, methods dispensing with suprapubic drainage and its inconvenience could be adopted with advantage.

Discussing the transvesical operation devised by S. H. Harris, R. G. S. Harris[1] stressed the importance of "clean intracapsular removal" of the adenomatous tissue. Positive hæmostasis by suture and plastic reconstruction of the cavity went far to prevent postoperative sequelæ, and urinary fistula and incontinence were said to be rare. Mortensen[2] described transurethral prostatectomy and dealt with the untoward events which followed any form of prostatectomy and also with those specifically related to the operation of resection. The latter included urethral stricture, hæmolysis (from leakage of irrigating fluid into open venous sinuses), and persistent postoperative infection; but they were uncommon in expert hands. Contrasting the technique of retropubic prostatectomy with the transvesical operation, Kirkland[3] made some interesting comments on the comparative freedom from risk in opening up the prevesical space and interfering with the prostatic venous plexus. The particular Australian bogy of osteitis pubis in relation to the retropubic operation was largely discounted at the symposium; and the short period of catheter drainage required after this operation was regarded as a contribution to the early restoration of urinary continence.

It is hard to draw any very significant comparative conclusions from the views of these Australian surgeons. As Caine[4] pointed out in a recent review of the late results and sequelæ of prostatectomy, the surgeon of today has a choice of many technical procedures, all of them well tried and each with its distinguished advocates. Each has produced good results in the hands of those familiar with it, and the patient with prostatic trouble may now reasonably expect both relief from his symptoms and freedom from postoperative distress.

MORPHINE-LIKE DRUGS

Few drugs have been more closely studied from the point of view of the relationship between molecular structure and pharmacological activity than morphine. When the structural formula of morphine was established, many simpler structures could be identified within its complex molecule. For many years potent analgesics were sought by synthesising phenanthrene derivatives, but the results were very disappointing. The discovery of pethidine's analgesic properties was a big advance which focused attention on the resemblance of this apparently unrelated compound to morphine. Other types of compound were synthesised, including methadone, isomethadone, and the dithienylbutenylamines. In all, many hundreds of synthetic chemicals were prepared and tested for analgesic activity. All of these bore some structural relation to the natural prototype, morphine. Braenden et al.[5] have lately collected and summarised a mass of detail about the way in which alterations in the chemical constitution of several groups of compounds related to morphine modifies their analgesic potency. This valuable work shows that it is now possible to point to certain chemical features which are shared by drugs with true morphine-like analgesic activity. This activity is associated with a tertiary nitrogen atom carrying a methyl group or another group which must be of low molecular weight. There is a central quaternary carbon atom, none of the valencies of which are connected with hydrogen; and the carbon atom bears on one valency either a phenyl group or a group which is isosteric with phenyl. Maximum analgesic activity seems to be achieved when the tertiary nitrogen atom is separated from the quaternary carbon atom by a chain of two carbon atoms. Yet some compounds with these very features have no morphine-like properties and it is still not possible to predict with confidence that a particular chemical configuration will act in this way. The picture is obviously incomplete, and it becomes a very preliminary sketch when we realise that though in time we may be able to identify analgesic properties in a molecule from an examination of its chemical and physicochemical properties we still know little or nothing about the receptors with which it combines and reacts.

INTERSTITIAL MYOCARDITIS

Interstitial non-rheumatic non-suppurative myocarditis was well known to pathologists of the 19th century. It was considered to be a complication of bacterial infections, usually typhoid fever and streptococcal infections. In 1899 Fiedler[1] considered that the isolated form of acute interstitial myocarditis was a special disease, to which his name is now often attached. Saphir,[2] after a thorough examination of his own material and of the literature, concluded that isolated myocarditis was not a specific disease but the outcome of various infective and toxic processes.

Because there are seldom any characteristic gross anatomical findings, the condition may have been often overlooked at necropsy. When such changes are present, they consist of enlargement of the heart due to eccentric hypertrophy or to dilatation alone, mottling of the myocardium by pale purple or pinkish grey spots, and occasional red spots of hæmorrhage. But usually only the histological examination reveals the real nature of the disease. The characteristic finding is interstitial cellular infiltration, with predominance of round cells. The infiltration is more often focal than diffuse. The clinical picture was well described by Williams et al.,[3] who studied 14 patients of ages ranging from twelve days to five years, and by van Creveld et al.,[4] who recorded 11 examples of this condition in childhood. There is acute circulatory and respiratory distress (without significant fever), cyanosis, extreme tachycardia with a very small, weak, thready pulse, no murmurs, sometimes gallop rhythm, and usually enlargement of the heart. The electrocardiogram shows a low voltage, RST segment, flat or inverted T wave, and supraventricular tachycardia. The disease may be confused with glycogen storage disease of the heart, with one form of fibroelastosis, and with the disease of the coronary arteries of the newborn that is known by various names (that recently proposed by Zischka[5] is "arteriopathia calcificans infantum").

Important progress in the understanding of these form
myocarditis came from experiments which show the

In England Now

There is nothing like being a patient in your own hospital to solve the mysteries of your work For years I have been puzzled by the regular, if rare, arrival in the anæsthetic room of a patient with a full stomach Elucidation came to me as I was lying in bed pleasantly drowsy from my premedication awaiting the arrival of the theatre trolley A cheerful patient appeared round the curtain

'Here y are guv, a nice cuppa tea with sugar an all" -

'No thanks I replied, I m just going to the theatre and they don t let you drink

Now look 'ere chum", the tempter persisted ' It ain t the surgeons who are keen on this no food racket it s only the anæsthetists and no one takes any notice of them

Too true, ' I agreed sleepily, I am one '

Our hospital general typists office is typical of the Welfare State—no pen and no inkpots but two teapots, one coffee-pot and countless milk bottles

Parliament

At the standing committee on the Clean Air Bill on Feb 21 Mr Enoch Powell, parliamentary secretary to the Ministry of Housing and Local Government said it was proposed that the appointed day for the prohibition of " dark smoke " from any chimney should be early in 1958 The Bill provides that for seven years after legislation is passed exemptions shall be given when smoke is caused by the nature of a building or its equipment and not by failure to maintain them properly Mr A L Blenkinsop felt that with this exemption there would be little or no sense of urgency in the campaign to end air pollution but an Opposition amendment to reduce the period to three years was turned down

The Secretary of State for Scotland announced that as part of a two year campaign against tuberculosis he had invited Glasgow Corporation to conduct a city wide survey by mass radiography in March, 1957 Besides the 10 mass radiography units normally in use in Scotland 20 more would (he hoped) be lent by England and Wales for five weeks The other three Scottish cities and many areas in the industrial belt, would later be offered facilities for similar surveys

The Minister of Labour has announced that, on the advice of the Industrial Health Advisory Committee, a pilot industrial health survey is to be made of the pottery industry Last year it was announced (see *Lancet*, 1955, ii 610) that a similar pilot survey would be made at Halifax

There can be few of us who would not shrink from such a task. When Bernard Shaw wrote of *The Doctor's Dilemma* he could scarcely have guessed the reality of the plot. You will remember, the choice between the deserving colleague and the undeserving genius was not made lightly. Your choice, made from the meagre data on a slip of paper, is all the harder. I do not blame you for making a compromise. What can be simpler than to share the chair?

For my part I've always thought it my duty to put relief of suffering before everything else—even before the saving of life. It comforts me to know that, however incurable the disease, there is always something I can do. But for once I am powerless.

Anæmia is not usually a distressing complaint. Mrs Neal, however, is elderly and her arteries are hard and narrow. Her lungs are emphysematous, her heart is weak, her eyesight is poor. Her gastric mucous membrane is atrophic, and her digestion is not good. When her hæmoglobin falls below 60% she begins to get angina, breathlessness, and cramp. She loses appetite and weight, and even medicine gives her indigestion. As her legs gradually swell, so her body slows and her mind becomes dull. Finally, her hæmoglobin 35%, she is reduced to the picture of abject misery that I know so well. She comes to us for help. And what do we do? We transfuse her till her hæmoglobin is 65%, and five days later the whole wretched story begins all over again. You have made your compromise.

I admit we are no nearer to a solution, although I hope I have convinced you that, of the possibilities, at least two are unacceptable. Surely there must be an answer to the problem that does not clash with one's ideals? I should willingly do anything in my power to help you find it.

Forgive me for taking you from your microscope.

Yours ever,
H. B.

Letters to the Editor

Vaccinia versus Poliomyelitis.—Colonel Morhouse (Feb 25) says that in the United States, though vaccination against smallpox has usually taken place by the age of 6–7, children of that age are regarded as particularly liable to contract poliomyelitis. Can he give us an idea of what proportion of these vaccinations are performed in infancy? If, as in this country, vaccination is commonly performed at 3–6 months, it could not be expected to give full protection against poliomyelitis at school age.

My own data suggest that, though smallpox vaccination several years previously *may not prevent poliomyelitis, it may* modify the illness so that paralysis is avoided. In 1955 in this area 35 children aged 4–7 years contracted poliomyelitis (paralytic or non paralytic). Of the 25 in whom there was no paralysis after the illness, 19 had been vaccinated in infancy, while 6 had never been vaccinated. Of the 10 with paralysis, 4 had been vaccinated in infancy while 6 had never been vaccinated, and it is noteworthy that in all 4 vaccinated children paralysis was slight, whereas in all 6 unvaccinated children it was severe.

Since in my area about half the children are vaccinated against smallpox, it may be asked why, of 25 children with non paralytic poliomyelitis, as many as 19 should prove to be vaccinated. A possible explanation is that children vaccinated in infancy are for several years so fully protected against poliomyelitis that they do not contract the disease in any form and therefore do not acquire any specific immunity to it. Hence, compared with children who have never been protected by smallpox vaccination, they may be more liable to contract poliomyelitis at school age—though the waning effect of the vaccination may still suffice to save them from paralysis.—D. P. MacIver, M.D. (Weybridge, Surrey.)

Leptospirosis.—As a veterinary surgeon I see many cases of leptospirosis in the dog, mostly due to *Leptospira canicola*, more infrequently to *L. icterohæmorrhagiæ*. My experience is perhaps relevant to the correspondence on the value of penicillin in the treatment of the disease in man (Feb 11 and 18).

I find that penicillin causes temporary remission of symptoms, lasting for about 36–48 hours, followed by relapse. Dark ground examination for the causal organism is often positive after several days' administration of penicillin in h- doses. I am inclined to think that acute cases responding to some degree to penicillin become chronic, usually show eventual nephritis with uræmia; a further acute attack is not uncommon. Administration of streptomycin and oxytetracycline concurrently produces very satisfactory, perman- results with gratifying speed.

Leptospirosis in the dog is far from uncommon, as many of my colleagues have found to their cost. It is surprising that more cases do not appear among those devoted to dogs at close quarters—children in particular. I make a point of handling suspect urine with care.—R. T. Dawson, M.R.C.V.S. (Ashington, Northumberland.)

Mass Radiography.—I have read with interest and no little amusement Dr Brailsford's letter (Feb 25). So far from being "the most serious" objection to mass radiography, I think it will be a great advantage if this method "leads to students being taught that active progressive tuberculosis can be present without signs or symptoms." This a hard fact which we, in the chest service, have all learnt by experience and I could only wish that it had been emphasised when I was a student.—G. I. Rees Jones, M.R.C.S., director, mass radiography units 7B and 7F (Oakwood Hospital, Maidstone.)

Production of Codeine.—I am glad Dr Hamilton (March 10) agrees with me that the codeine in tab codein co does not enhance the analgesic effect, but surely if his so-called new drug, *n* acetyl *p* aminophenol, is only of equal analgesic value why does he not stick to tab codein co without the codeine? At present a hundred (0.5 g.) tablets of *n* acetyl *p* aminophenol ('Panadol') cost 10*s.* 11½*d.*, which is the price of a thousand (gr 10) aspirin tablets.

There is, however, a far more important reason why Dr Hamilton should temper his present enthusiasm. *n* Acetyl *p* aminophenol is merely another way of saying *p* hydroxy acetanilide—a word full of sinister implication which conjures up memories of 'Antifebrin', 'Daisy Powders', and deaths from agranulocytosis.

Acetanilide was excluded from the 1954 *British Pharmaceutical Codex* because of its toxicity, and Daisy powders are no longer available. It will take much to convince me that Dr Hamilton's new hydroxylated "Daisy pill" is completely above suspicion.—Eirian Williams, M.R.C.P. (London Hospital, E.1.)

Streptonivicin.—May I comment on your annotation (March 3) reporting the common identity of streptonivicin ('Albamycin') cathomycin ('Cathocin'), crystallinic acid ('Cardelmycin'), and albomycin?

H. Welch and W. W. Wright (*Antibiot Chemother* 1955 5, 670) reported the common identity of streptonivicin, cathomycin, and crystallinic acid, based inter alia on unequivocal evidence—the infra red absorption spectra of the crystalline antibiotics. There is, however, no report that albomycin, first described by G. F. Gause and M. G. Brazhnikova (*Nov Med Mosk* 1951, 23, 3) is identical with these other three antibiotics, nor that the antibiotic strains *Streptomyces niveus* and *Actinomyces subtropicus* are identical.

Streptonivicin is a dibasic acid (H. Hoeksema et al. *J Amer chem Soc* 1956, 77, 6710) containing C, H, O, and N only, active predominantly against gram positive bacteria, inhibiting staphylococci at dilutions of 1/750,000 to 1,3,000,000. Streptonivicin by mouth can protect infected animals. Albomycin, on the other hand (G. F. Gause, *Brit med J* 1955, ii, 1177), is a cyclic polypeptide, thought to be an "imitation" of some iron containing respiratory enzyme in albomycin sensitive bacteria, contains 4.16% iron, is active against gram positive bacteria, in particular staphylococci at a dilution of 1/700,000,000, and is also active against certain gram negative bacteria. No report on the effectiveness of oral albomycin is available, and it is likely, in common with other "polypeptide" antibiotics, not to be absorbed from the alimentary tract.

It may be added that crystallinic acid (cardelmycin) has been previously known as antibiotic PA93 of the Pfizer Laboratories (H. Wright, W. W. Wright, *Antibiot Chemother* 1955 5, 670).

A further point of difference between the two antibiotics is their colour; streptonivicin is white, whereas albomycin (presumably on account of the iron content) is red.—K. A. Lees, F.P.S. (Glaxo Laboratories Ltd., Fermentation Research Division, Sefton Park, Stoke Poges, Bucks.)

Hypofibrinogenæmia in Pregnancy

Serious loss of blood from the uterus after labour is one of the major complications of childbirth and one of the commonest causes of death of the mother The collection of incidents and information over the past ten years has led obstetricians to recognise that the immediate cause of the disastrous uterine hæmorrhage is often a temporary abnormality of the blood-clotting process, and furthermore, if treated in time, these hæmorrhages can be stopped and the patient saved by other than local methods Ratnoff et al[1] have recently reviewed the evidence and come to the conclusion that abnormal blood clotting is the usual cause of fatal uterine postpartum hæmorrhage

In normal pregnancy and labour blood-clotting processes are little changed There are no significant changes in the platelet count and no unusual fibrinolytic activity in the plasma The fibrinogen content of the plasma rises slowly by about one-third during the pregnancy After labour it is, as Barnes[2] pointed out, the contraction of the myometrium that ensures proper hæmostasis at the placental site, the most striking examples of this have been seen in patients with thrombocytopenic purpura[3] and in a young woman with hæmophilia[4] who have successfully completed labour without any unusual *immediate* blood-loss, subsequent blood-loss in these patients came from damage to other parts of the genital tract that are not supplied with such an efficient vasoconstrictor apparatus as the uterus The obstetric conditions especially liable to be followed by excessive uterine hæmorrhage, are premature separation of the placenta, amniotic-fluid embolism, missed abortion with retention of a dead fœtus, and eclampsia It has been discovered that, except in eclampsia, the blood-clotting abnormality in all these conditions is a gross deficiency of fibrinogen, and the explanation proposed is that thromboplastic material reaches the maternal circulation Experimental evidence for this hypothesis has been known for some time Ratnoff et al[1] quote experiments by Mills in 1921 which showed that intravenous injection of tissue-thromboplastin caused a decrease of plasma fibrinogen, and in fact gradual infusion of thromboplastin led to complete defibrination of the animal, the fibrinogen level in the plasma returned to normal twenty-four hours after the infusion ceased There is also evidence that amniotic fluid and placental tissue have considerable thromboplastic activity Hæmorrhagic symptoms appear when the plasma-fibrinogen level falls below 100 mg per 100 ml there is often bleeding from venepuncture sites and subcutaneous hæmorrhage, and postpartum uterine bleeding may be severe and prolonged and the consequences grave

Premature separation of the placenta is the commonest cause of uterine bleeding in pregnancy and is said to occur in from 1 in 85 to 1 in 250 pregnancies The condition has been known for twenty years to be associated with hypofibrinogenæmia, but only lately has this point received much attention The cause is thought to be the passage of thromboplastic material from the placenta into the maternal blood-vessels, where intravascular clotting takes place, and this continuing process uses up the plasma-fibrinogen, but this explanation is not accepted by all authorities In amniotic fluid embolism, the sudden onset of labour and its rapid course is sometimes followed by severe uterine hæmorrhage, and hypofibrinogenæmia is often found, Jackson et al[5] have recorded 8 such cases The latest syndrome to be associated with plasma-fibrinogen depletion is missed abortion with retention of a dead fœtus in the uterus Weiner et al[6] described 3 cases of severe uterine hæmorrhage following spontaneous delivery of a dead fœtus, in which hypofibrinogenæmia was found in the mother, they thought that rhesus incompatibility was also concerned, but subsequent findings do not support this view Pritchard and Ratnoff[7] studied 31 patients who remained undelivered for three or more weeks after apparent intra-uterine fœtal death in 23 there was no evidence of critical depletion of fibrinogen (i e, a level below 150 mg per 100 ml), though in 7 patients the fibrinogen level fell steadily throughout the pregnancy, in the remaining 8 patients the fibrinogen levels became dangerously low After delivery the plasma-fibrinogen rose rapidly to normal in forty-eight hours Experience has shown that hypofibrinogenæmia does not develop when the fœtus dies before the fourth month of gestation, and it does not appear until at least five weeks after the apparent death of the fœtus

Lately cases of hypofibrinogenæmia in pregnancy have been reported in this country Barnett and Cussen[8] described 2 cases of concealed accidental hæmorrhage causing precipitate labour, qualitative tests showed a low fibrinogen level Barry et al[9] gave details of 6 cases of complications of pregnancy associated with hypofibrinogenæmia, and in 1 of them none of the recognised syndrome was present Kelsey and Muirhead[10] also described fibrinogen deficiency in an apparently uncomplicated case of postpartum hæmorrhage O'Driscoll and Lavelle[11] had a patient with a retained dead fœtus and low plasma fibrinogen, low platelet-count, and an active fibrinolysin in the plasma. When induction by an oxytocin drip failed, a hysterectomy was carried out, and it is interesting that no large retroplacental hæmatoma was found, because such a hæmatoma has been suggested as the source of the thromboplastin which reduces the plasma-fibrinogen Kimbell and Ghosh[12] found afibrinogenæmia associated with massive postpartum hæmorrhage after a lower-segment cæsarean section

In the matter of treatment, Ratnoff and his colleagues agree with Moloney et al[13] that human fibrinogen

ar hypertrophy An apical diastolic murmur which ometimes confuses the diagnosis, and which may indeed e due to coincidental abnormalities of the mitral valve sually indicates a large shunt with an excessive blood-low through the left heart The shunt is usually small, ut in the more severe cases, with pulse-pressures between 0 and 100 mm Hg, it may amount to 50–70% of the left entricular output There is general agreement that urgical closure of a patent ductus is almost always advisable both because of the risk of bacterial endocarditis and because of the natural history of the disease Admittedly, large shunts can be tolerated for a surprisingly long time, and spontaneous closure is possible even after the age of thirty, but deterioration with heart-failure is to be expected, as CAMPBELL has found in the third or fourth decade[1]

An important and peculiar complication of patent ductus arteriosus is pulmonary hypertension[2-5] It is perhaps less common with patent ductus arteriosus than with other congenital communications such as atrial or ventricular septal defects[6], but there is evidence to suggest that at least 1 case in 10 may be affected Two forms can be recognised one which develops gradually and is usually mild, and the other which begins early and is severe Its effect is to reduce or abolish the shunt or even reverse its usual direction, and the clinical signs are modified accordingly In the mild form the continuous murmur may persist, although it is usually shortened to a systolic murmur, and it often disappears altogether in the severe form The pulse-pressure tends to remain large, but symptoms and signs of pulmonary hypertension develop and may even predominate Attacks of respiratory infection, with cough dyspnœa, and hæmoptysis, are common, and ultimately there is right sided heart-failure The pulmonary second sound is loud and accentuated, and it is accompanied by a palpable impulse in the second left intercostal space The characteristic parasternal lift of a hypertrophied right ventricle can usually be found, and the electrocardiogram often indicates right ventricular or combined right and left ventricular strain Giant *a* waves can sometimes be seen in the jugular pulse, and a Graham Steel diastolic murmur of pulmonary incompetence may suggest a diagnosis of aortic incompetence unless the significance of the other signs is appreciated Reversal of the shunt usually causes cyanosis, which can be generalised but is often more pronounced in the lower limbs because of the entry of the ductus into the aorta beyond the left subclavian artery

Recognition of a patent ductus arteriosus combined with pulmonary hypertension can be difficult Where the continuous murmur persists the diagnosis should be possible clinically, but when the signs of pulmonary hypertension predominate, the diagnosis from other lesions, such as atrial and ventricular septal defects and primary pulmonary hypertension, can be made only after catheterisation and angiocardiography Indeed the possibility of an underlying patent ductus arteriosus makes such investigations essential in any patient with unexplained pulmonary hypertension, whether cyanosed or not, particularly in children Catheterisation by itself will sometimes be enough, for the catheter often passes easily through the ductus, especially if the shunt is reversed In uncyanosed cases there should be a higher oxygen saturation in the pulmonary artery than in the right ventricle, and an angiocardiogram may show simultaneous filling of the pulmonary artery and the descending aorta

The cause of pulmonary hypertension in patent ductus arteriosus is debatable Mild hypertension coming on in middle life may be due to an increase in pulmonary blood flow, but this can hardly account for severe hypertension, since shunts amounting to 50% of the left ventricular outflow often persist uncomplicated for a number of years Pulmonary resistance is always increased when the shunt is reversed, and this increase is almost certainly what produces severe pulmonary hypertension Why resistance should increase is not clear histological studies have suggested that repeated pulmonary embolism and even acute pulmonary arteriolitis are occasionally responsible but persistence of a fœtal pattern of thick-walled and muscular arteries has been suggested by EDWARDS[8, 9] as a more likely explanation On the other hand, widespread arterial occlusion by fibrous tissue, associated with the formation of new and probably anastomotic vessels, as recently described by BREWER[10] suggests that the vascular abnormality is sometimes acquired as the late result of an earlier functional change

Opinion varies about the treatment of patent ductus arteriosus with hypertension The need for operation is clearly increased by slight hypertension, but it is debatable in the severer grades Where there is cyanosis indicating a reversed shunt, operation is contra-indicated since the ductus seems to act as a safety valve Some people advocate ligation in all cases with left-to-right shunt, claiming that its effects are beneficial even some time afterwards Others prefer to be guided by the effects on the pulmonary pressure of digital compression of the ductus at the time of operation, since success depends upon the reversibility of the hypertension The technical difficulties may be formidable because the ductus is often short and wide and may contain calcium, which can spread on to the pulmonary artery or the aorta and make them liable to tear

---

Annotations

BRITISH POLIOMYELITIS VACCINES

THE department of biological standards of the National Institute for Medical Research is responsible for carrying out the safety tests on the poliomyelitis vaccines soon to be used in this country, and the director of the department, Dr W L M Perry, has sent us some detailed technical information about the vaccines In our present difficulties it is impossible to publish this information in full but Dr Perry s text will be found in this week s *British Medical Journal* The most important modification from the strains of virus used in the United States is the adoption of an alternative type 1 virus which is considerably less virulent than the original strain, a change which should greatly increase the safety of the vaccines The method of vaccine production and formalin treatment are similar to those used elsewhere, and the British vaccines will be subjected in duplicate to all the safety tests adopted in the U S.A, including the use of cortisone treated monkeys As Dr Goffe emphasised in our last issue the American vaccine which has met these new requirements has been given to some 10 million children without any detectable ill effects It is hoped that British vaccines will be at least as potent as American vaccines and Dr Perry calls for the support of the medical profession in this first step towards the safe and effective control of poliomyelitis in this country

In the past few days general practitioners received from the Ministry of Health a note giving information about poliomyelitis vaccination. The Medical Research Council has been invited by the Ministry to assess the efficacy of the British vaccines and medical officers of health will be asked to make a brief report on each notified case paralytic or non paralytic, in their areas in children born in 1947-54 type, once the specific antiserum became available, and both found it in babies outside the hospitals in which they worked ROGERS commented on his good fortune in having specific serum so quickly available, since TAYLOR had already prepared it against a strain isolated a few months earlier

This recent work illustrates the importance of continuing the search for new serotypes SMITH[7] has described how these various types have been prevalent in different areas at different times and it is certain that in the future more serotypes will be identified and added to the list of those which are known to be pathogenic in babies

Visiting In Mental Hospitals

To be happy, we all need to feel secure, and insecurity has long been recognised as one of the most potent causes of illness The overt causes of personal insecurity are plain to see, and, given the means, easy to treat But, just as social reformers have learnt that money is no substitute for employment, so psychiatrists know that their patients' emotional troubles are seldom cured, though they may be eased, by the relief of practical difficulties

Whether we like it or not, we all start life as members of a group, and most of us are fortunate enough to spend at any rate the first years of life in the smallest unit of that group—the family As the nucleus of personal security, there seems to be no adequate substitute for the family, and we have abundant evidence of the ill effects of the absence of family ties We know too, how much support these ties can give in illness—and especially mental illness, when the sense of security is so often lost It is a pity, therefore, that the psychiatrist in a mental hospital, though he is well aware of his patient's family and often of their need for his advice, should often have difficulty in meeting them In so far as mental hospitals remain geographically and spiritually isolated, their doctors must deal with the patients' social problems by artificial methods group treatment is only a substitute for family treatment The promising results in the treatment of all types of mental illness in day hospitals and small units in urban areas may well be due as much to the closer contacts between the doctor and the family as to the preservation of the patient's social ties brought about by the ease of association with relatives and friends In other mental hospitals, for their contacts with the patient's family, the doctors must largely rely on visiting days The easier it is made for relatives and friends to visit a patient, the easier it is for the doctors to establish contact with them

Frequent visiting is also directly helpful to the patient A child who refuses to "settle down" in hospital was formerly considered neurotic, but the need to maintain family contacts has now been accepted, and by permitting daily visiting much has been done to mitigate the harm caused by separating children from their parents But, as Mr WOODLEY points out on another page, it is equally important that the adult patient in a mental hospital should not lose touch with home Other considerations apart, the experience of illness changes a patient, and relatives should have the time and opportunity to adjust to this change while he is still in hospital

The gravest problem in the modern mental hospital is the reablement of the patient who has lost touch with the outside world Modern methods of treatment have so far reduced the length of stay of the average patient that "settling down" is no longer essential to recovery indeed for not a few it is a danger to be avoided Daily contact with friends and relatives, whether for social or therapeutic reasons, can do little harm and may do much good An increasing number of mental hospitals already allow, or even encourage, daily visits from relatives, and there are no insurmountable reasons why all should not do so

Annotations

FORCES' MEDICAL AND DENTAL SERVICES

IN 1953 the Minister of Defence appointed a committee under the chairmanship of Viscount Waverley, to report on the medical and dental services of the Armed Forces The committee, whose medical members are Sir Harold Boldero and Sir Arthur Porritt, has now reported[1]

The question whether the three medical branches should be amalgamated the committee answers with an emphatic No, but, it says, joint use of hospitals should be extended, in the United Kingdom unnecessary duplication should be avoided, and the Services should consider establishing a specialist hospital for traumatic surgery Both the Army and the Air Force should have specialist sections in which officers would continue in their specialist work for their whole career, with the chance of attaining the rank of at least colonel (or group captain) The dental branches should be further coördinated, and the prospects for dental specialists improved The pay of lieutenant and captain medical officers should be increased to conform with the scales lately announced for combatant officers (this involves increases of from 5s 6d to 7s 0d a day) Increases for higher ranks are also proposed The pay of dental officers should be the same, rank for rank, as that of medical officers

The committee's many recommendations would have the effect of enhancing the professional and financial attractions of the Services, and thus of stimulating recruitment

INFECTION IN HOSPITAL

CLEAN air, clean food, clean instruments this is Dr Maurice Mitman's recipe for averting infection in hospital In his presidential address to the section of epidemiology and preventive medicine of the Royal Society of Medicine on March 16, he showed that this is no cheap recipe, but he also questioned whether hospitals are making the fullest use of the ingredients at their command Nowadays of the infectious diseases only smallpox calls for rigid isolation in a separate hospital, other infections can be treated side by side in the modern isolation hospital with proper nursing techniques General hospitals do not apply the principles of isolation rigorously enough Cases of non tuberculosis respiratory infection should be classified and, like the tuberculous, segregated Likewise patients with early poliomyelitis should be isolated These and other infectious diseases Dr Mitman pictured as being handled increasingly in infectious disease units attached to general hospitals Concerned at the difficulty in keeping the air clean in general hospitals, Dr Mitman is attracted to the idea of wards as domitory units (an idea made more practicable by early ambulation) This involves an increase in ancillary rooms which, by adaptation, should be extended at the expense of beds Among such rooms should be an examination room and a treatment suite, on the lines of an operating theatre suite, including clean and dirty utility rooms Soiled dressings could, if dry, be incinerated in the ward, if wet, enclosed in destructible waterproof containers To prevent losses, soiled linen is still sorted in wards—a practice conducive to infection Infant feeds should be prepared under aseptic conditions in a formula room In hygienic standards, notably in the kitchen hospitals should give a lead to industry hitherto such a lead has been lacking Dr Mitman emphasised that both staff and patients are especially liable to infection in the ward and the kitchen, for the staff the laundry is a special hazard

WOUND HEALING

IT now seems that epithelium is the prime mover in the the healing of an incised wound In demonstrating that epidermal cells pour downwards into the wound long before connective tissue regeneration has started, Gillman et al[1] have upset the view that connective tissue repair precedes epithelial regeneration Their work has been extended to excised wounds in areas from which split skin grafts have been taken Here again the raw surface is covered at the out experiments justify, in his view a far larger investigation in an area with a population of at least a million and lasting five to ten years so that patients may be adequately followed up

NON-EXPLOSIVE ANÆSTHETICS

It seems that the risk of an explosion during an operation is of the order of 1 in 485,870 [1] This very occasional hazard can be eliminated only by the routine use of non explosive anæsthetic agents There are many such drugs, but usually several must be administered in combination

In 1951 Cullen and Gross [2] reported that the non explosive gas, xenon, was an efficient anæsthetic agent in man, being a little more potent than nitrous oxide Cullen et al [3] have shown that it produces only very slight biochemical and physiological disturbances during clinical anæsthesia maintained for as long as 2 hours 21 minutes Now Bracken et al [4] have confirmed experimentally the safety of brief administration of xenon and have designed an apparatus for investigating the long term effects of this and other rare gases No toxic effects were found macroscopically or microscopically in a rabbit which breathed xenon for 48 hours

Xenon is extremely expensive and is not potent enough to be of practical value as an anæthetic, but pilot investigations of this sort are important since there is a definite need for an all purpose, non explosive inhalational anæsthetic

HEROIN

The case against banning heroin was presented fully to the Society for the Study of Addiction on Feb 21 Mr Lawrence Abel said that in treating cancer one needs as many drugs as possible so as to ring the changes 10–15% of people cannot tolerate morphine, and when a patient needs heroin he does need it Morphine can cause spasm of the bile ducts so that pressure is built up, and he thought the high incidence of trouble after cholecystectomy in the United States may be due to using morphine instead of heroin Dr A H Douthwaite said that, unlike *morphine*, heroin does *not* cloud the mind and allows people to attend to their affairs to find a drug which relieves pain, produces euphoria, and does not impair the intellect, yet does not produce addiction, would be impossible Because morphine so often induces vomiting, he has forbidden its use in his wards in cases of gastric hæmorrhage Dr Reginald Hale White pointed out that in incurable disease euphoria may be as valuable as freedom from physical pain when heroin is given the whole household cheers up Dr J A Hobson believed that if heroin ceases to be obtainable from medical sources the price will rise to a level at which professional drug pedlars will be attracted, they will smuggle in more of the drug and it will be worth their while to produce more addicts Prof A D Macdonald concluded that as analgesics, none of the substitutes are quite in the same class as heroin, and there is no really well established case for suppressing it

Two of the advertised speakers being absent, Prof P O Wolff, formerly of the World Health Organisation, was left almost unaided to state the case in favour of the ban[5] In answer to questions he explained that by its constitution W H O, as an essentially medical body, has no responsibility for controlling the illicit drug traffic, and is concerned simply with drug addiction arising from medical practice Even the United Nations cannot impose a ban they can do no more than ask governments to coöperate Dr Wolff believes that doctors must be free to prescribe what they think necessary, and he said that governments which have banned heroin (including that of the U S A) do in fact keep small supplies which are obtainable by doctors who think the drug indispensable for a particular patient He believes too that a government should not impose a ban without the agreement of the medical profession But he pointed to the example of Switzerland, which in 1931 declared heroin indispensable, yet twenty years later abolished its use – not because Switzerland had an addiction problem of her own but because Swiss doctors no longer found heroin a necessity and the government wished to coöperate with other countries in suppressing the drug, in order to "fulfil a humanitarian task which is in keeping with its traditions" Apart from the United Kingdom, only four countries out of some eighty members of W H O have not declared their willingness to dispense with heroin, and Professor Wolff hoped that on further consideration the profession in this country too will find heroin "ripe for replacement" Among the substitutes for it he drew attention particularly to the usefulness of dextromethorphan for cough and of levorphan for pain, which he thought worth further trial here

Mr Abel seemed to resent any suggestion that British doctors may be less than fully informed on anything that might benefit their patients, but Sir Weldon Dalrymple Champneys felt that they have at any rate shown regrettably little interest in the treatment of intractable pain with cobra venom, which in some cases gives remarkable relief Dr Jeffrey Bishop regarded the proposed international ban on heroin as an attempt to bolster up the policy of the head of the (non medical) American Narcotics Bureau—a policy which he said was increasingly discredited at home To which Professor Wolff replied (1) that each delegation at the Commision of Narcotic Drugs of the Economic and Social Council of the United Nations acts on the instructions of its own government; and (2) that the American Medical Association, a body which certainly does not take orders from the Narcotics Bureau has not opposed the Congressional prohibition of heroin in medical practice

Letters to the Editor

Poliomyelitis Vaccination —Dr Goffe, in his letter last week, estimates the chance of young children contracting paralytic poliomyelitis as 1 in 3000 per year, and hopes that the British Salk type vaccine will reduce this to 1 in 12,000 per year In order to prevent 3 paralytic cases 12,000 children must each be given two or more injections of inactivated virus This might be worth while if the protection lasted, but unfortunately it may only persist for a year or two What will be the situation after five years as regards the millions of American children who have been given the inactivated virus? Will the partial protection be maintained, lost, or even reversed? It seems to many that the long term prospects for those now being given the Salk type vaccine are so uncertain that the present American programme may be correctly described as a gigantic gamble —W RITCHIE RUSSELL, F R C P (Oxford)

Barbiturate Poisoning —Your leading article (Feb 18) encourages me to draw attention to Gould's work in the treatment of this condition His *article quoted in your leader* was the first of a series in which the clinical scope and physiological rationale of the treatment of acute barbiturate intoxication and allied conditions were discussed (J Gould *Lancet*, 1953, i, 570, *Brit J Addict*, 1954, No 1, *Proc. R Soc Med* 1954, 47, 215 R W Armstrong, J Gould, *J ment Sci* 1955, 101, 70 J Gould B S Cooper, *Med Pr* 1955, 234, 138) Gould maintains that intracellular brain katabolism is impeded in these states, and the later work of R A Hunter et al on vitamin B_1 (*Lancet*, 1955, ii, 1353) supports his clinical deductions Novelli and Soodak suggest that, for the reconstitution of dissociated enzyme and co enzyme systems, up to 1000 times the normal tissue concentrations of co enzyme —usually a B vitamin—may be required (Biochemistry and Physiology of Nutrition, vol 2, p 328) This is in close conformity with Gould's clinical observations and practice

Physicians unfamiliar with these ideas are necessarily puzzled by the enormous doses of vitamins recommended by Gould *and his co workers in my department*, but the high dosages are clinically demanded and would appear to be scientifically justified by the work of Novelli et al In other words, in the treatment of barbiturate intoxication by high potency vitamins we are no longer thinking of these in terms of normal nutritional needs, but are using them as powerful biochemical agents

Another feature of the technique which has bothered critics is the continued administration of large amounts of balanced vitamins after the initial injection The reason for this becomes clear when it is remembered that the gut and tissue fluids remain for a very long time reservoirs of absorbable barbiturate which can only be exhausted by gradual absorption into the blood stream

"Conservative' methods of treatment were advocated by S Locket and J Angus (*Lancet*, 1952, i, 380), but it is surely desirable on physiological grounds to reduce the time during which brain cells are subjected to biochemical insult gitic. In striking contrast to Ingraham's experience,[11] Desmit found no subdural effusions.

When powerful antibiotics were first introduced, the problem of purulent meningitis seemed to be solved, but plainly there is as yet no agreement about the course, treatment, and outcome of these infections. Ounsted[12] has pointed out that the number of children with brains mutilated by meningitis is increasing rapidly. Such children are prone to gross forms of epilepsy and disordered behaviour, and quite apart from the personal tragedies involved, the community must bear this costly burden for many years. There is a clear indication for a carefully planned and well controlled study of the treatment and outcome of purulent meningitis.

Occasional Survey

GASTRO-INTESTINAL COMPLICATIONS OF ORAL ANTIBIOTICS *

MINOR intestinal symptoms are not uncommon when antibiotics are given by mouth. Any part of the alimentary tract may be affected—sore tongue and mouth, nausea, occasional vomiting, abdominal distension, diarrhœa, and the so called *anorectal syndrome*, which, incidentally, may persist for weeks after the antibiotic is stopped.[1 2]

PREDISPOSING FACTORS

The frequency of these complications, which may be as high as 30% or more,[3-8] depends on a number of factors. The most important of these is the breadth of the drug's antibacterial spectrum. The tetracyclines are therefore the worst offenders. Oral penicillin gives less trouble because it leaves coliform bacilli unaffected. Injected penicillin and streptomycin, singly or in combination, very rarely produce alimentary symptoms since very *little of either penetrates the intestinal lumen*.

The antibacterial spectrum, however, cannot be the only factor involved, since the spectrum of all the tetracycline drugs is virtually the same, yet it is generally agreed *that tetracycline itself is less likely to give rise* to complications than either chlortetracycline or oxytetracycline[7]; it is probable that chloramphenicol and neomycin, which have similar antibacterial spectra, are still less likely to cause digestive disturbances.[8] It seems that the difference is due to chemical irritation of the gut. Certainly the tetracyclines are very irritant on injection, not infrequently causing thrombosis when injected intravenously and considerable pain when injected intramuscularly, even when given with procaine. Chemical purity may have been a factor in the past. It has been *claimed that thrice crystallised chlortetra*cycline is better tolerated than the original impure preparations.[9]

Finally, the incidence of enteral complications is closely related to the dose of the drug and its duration. Finland and others[5] showed that symptoms occurred twice as often with a dose of 250 mg of chlortetracycline given four hourly as with the same dose six hourly.

PREVENTION

It follows that alimentary side effects may be minimised by:

(1) Interfering with the gut flora as little as possible. This implies using sulphonamides or penicillin by injection when suitable. It is highly important that when sterilisation of the bowel is required, only drugs effective against any locally endemic staphylococci should be used. It is asking for trouble to remove all the normally resident non-pathogenic bacteria from the intestine in an environment where resistant staphylococci are prevalent.

(2) Nausea and diarrhœa can be reduced by giving milk with *each dose of oral antibiotic*. Alkalis such as aluminium hydroxide and magnesium trisilicate, though effective, should not be used for this purpose since they interfere with absorption.[9] Several authors have reported that yogurt given in doses of one cupful *three or four times a day is effective, both in prophylaxis* and treatment of antibiotic-induced diarrhœa.[10 11] Perhaps yoghurt should be made from an antibiotic-resistant strain of lactobacillus. Various vitamin-B preparations have been recommended for these purposes, *but it is doubtful whether they are of much value*.[11-13] Cathartics should be avoided.[5]

(3) The *dose and duration of treatment* must be kept down to the minimum that is effective.

SUPERINFECTION

The vast majority of alimentary complications are due to minor disturbances in bacterial ecology and to the irritant effect of the antibiotic on the intestinal wall. They subside rapidly when the drug is withdrawn. However, in the past few years there has been a disturbing number of reports of superinfection by resistant organisms such as monilia[14-17] and staphylococci,[13 18-19] *which may become widely disseminated throughout the* body. Usually one or more broad spectrum antibiotics have been given, but *staphylococcal superinfection has occasionally followed the use of intramuscular penicillin and streptomycin in combination*[20-22] and in one unpublished non fatal case it followed a week's course of intramuscular penicillin alone. In two of three cases mentioned by Barber and Burston[23] no antibiotic at all had been given.

Clinically the syndrome is very like that of pseudomembranous enteritis reported occasionally in pre-antibiotic days, usually associated with postoperative shock.[18 24] In the unpublished case mentioned above the enteritis did in fact follow a thigh *amputation*, and it is difficult to be sure of the part the administration *of penicillin played in its development*. Though both are excreted to a small extent in the bile,[25 26] it is inconceivable that injected penicillin and streptomycin alone or together, could sterilise the gut. A more likely explanation is that these antibiotics, especially in combination, may virtually sterilise the nose, throat and respiratory tract, so promoting their colonisation by resistant staphylococci which gain a *foothold* in the alimentary tract through the patient swallowing his own secretions.

(3) Your reference to a paper by us (W J Dempster A M Joekes, *Quart J exp Physiol* 1953, 38, 11) as showing that transplanted kidneys with the ureters implanted into organs other than the bladder" deteriorate rapidly in function is inept This paper dealt exclusively with some problems of diuresis and antidiuresis in autotransplanted kidneys with skin ureterostomy

Work in this country has had as one of its major aims to confirm technical feasibility of transplanting kidneys, known since the turn of the century, and to establish the best site for long term survival and maintenance of function (W J Dempster A M Joekes, *Acta med scand* 1953, 147, 99 W J Dempster A M Joekes, N Oeconomos, *Ann R Coll Surg Engl* 1955, 16, 324) Reimplantation of the ureter into the bladder resulted in better function of transplanted kidneys, which showed indefinite survival times with normal function

It is surprising that you follow the paper from Boston (J P Merrill et al *J Amer med Ass* 1956, 160, 277) describing the successful homotransplantation of a kidney between identical twins, in failing to cite the only published work, done in this country, giving clear indications for the elective site for a kidney transplant —A M JOEKES, M R C P (London. W 1)

Obituary

Miss DIANA BECK

Miss Beck, neurosurgeon to Middlesex Hospital where she died on March 3 was one of the first women to be appointed to the consultant staff of a London teaching hospital which was not her own Born in 1902 in Chester of a family of Scottish descent, she qualified from the Royal Free Hospital London in 1925 Having taken the F R C S in 1930 she returned to the Royal Free as surgical registrar and lecturer in surgical anatomy, and she had already proved herself as a surgeon and teacher before she specialised in neurosurgery Shortly before the late war she began her apprenticeship in this exacting specialty with Hugh Cairns at Oxford In 1943 she was appointed neurosurgeon to the Royal Free Hospital She worked at Chase Farm and in Bristol where she had charge of an E.M.S neurosurgical unit She joined the staff of Middlesex Hospital in 1947

Prof L P GAMGEE

THE Gamgee family belong to the history of Birmingham surgery, and Professor Gamgee, who died on March 1 at the age of 87 belonged to the second generation His father Sampson Gamgee who joined the staff of the Queen s Hospital almost a century ago, will be remembered for his advocacy of dry infrequent dressing of wounds and also his promotion of the Hospital Saturday Fund Leonard Gamgee qualified in 1891 from Queen's College Birmingham and his first appointments were as assistant to the professor of surgery and as a resident at the Queen's Hospital He joined the staff of the Birmingham General Hospital in 1893 and later was appointed to the chair of surgery in the university His teaching was practical and effective He had the knack of setting out surgical principles clearly and entertainingly and the courage to set them out dogmatically, for he was unwilling to confuse his students with differing opinions and authorities As a colleague put it, his students were told what to do and when to do it and as often as not made to do it there and then" Gamgee belonged to the age of clinical rather than laboratory surgery and he was content to write little and practise much, treating patients rather than diseases

In England Now

O what can ail *The Lancet's* form
Alone and palely loitering?
The ink is wither'd from the page
And no printers print

News

Influenza like illnesses have been increasingly common in the past few weeks in many parts of the country In the north Cumberland Lancashire and Cheshire have been particularly affected Elsewhere the outer London area especially Kent and Sussex has been among the many areas involved Virus A has again been demonstrated in many outbreaks

On Feb 25 at a congregation of the University of Oxford the degree of D M was conferred on A W Frankland Margaret E H Turner Warwick and H A K Rowland and the degree of B M on Joyce Dutton

At recent examinations for the degree of M CHIR in the University of Cambridge the following were successful D A Bailey J M Davies C.O Henriques P F Jones D W T Roberts T M Robinson W F W Southwood

The University of Dublin is to confer the honorary degree of M D on Dr E R Boland and the honorary degree of M CH on Prof A K Henry

They can be minimised by attention to certain well-established principles

Occasionally superinfection with resistant organisms develops In recent years the staphylococcus has overshadowed the others in importance It may produce diarrhœa which, if urgent measures are not taken, may become choleriform and rapidly fatal

Emphasis is laid on the danger of disturbing the normal intestinal flora in an environment where resistant staphylococci are prevalent

Preliminary Communication

RITALIN AS AN ANTAGONIST TO RESERPINE IN MONKEYS

RESERPINE ('Serpasil'), an alkaloid originally made from *Rauwolfia serpentina*, has been given with benefit to many patients both in this country and in America, but there have been many reports of undesirable side-effects, including diarrhœa, nightmares, agitated depression, giddiness, anxiety, parkinsonian like tremor, asthma, and facilitation of convulsions Furthermore, it has been estimated that serious mental effects arise in about 5% of patients treated with reserpine—a finding that may cause some hesitation to prescribe the drug

We have found experimentally that the effects of large doses of reserpine are dramatically reversed by subcutaneous injection of 'Ritalin' (the hydrochloride of phenyl [α-piperidyl] acetic acid methyl ester), a new synthetic compound with a specific central stimulating component The interaction of ritalin and reserpine was observed *during studies on the effect of reserpine in monkeys*

We have so far used in our experiments nine monkeys—four *Macaca nemestrina* and five *Macaca mulatta*—adolescent or pre-adolescent animals, weighing 2 5–3 5 kg In each experiment 5 mg (2 ml) of reserpine was injected intramuscularly About three hours later, when the drug had produced a catatonic-like state, 20 mg (1 ml) of ritalin was injected subcutaneously

The result of injecting 5 mg of reserpine varied singularly little between different animals, except that in some the onset of symptoms occurred after about one hour and in others after nearly two hours When the reserpine was fully effective, the animals sat in a fœtal-like position with a parkinsonian like tremor and flushed hands, feet, and face Food was ignored or, if placed in the mouth, held between the teeth but not chewed Patellar and plantar reflexes remained present, and a very strong grasp reflex was established in all four extremities It was possible to place the monkey's body and limbs in bizarre positions, which were held Spontaneous activity was abolished, but response to strong stimuli such as a needle prick remained When an animal in this catatonic-like state was given 20 mg (1 ml) of ritalin, a striking change ensued in three *and a half to six minutes* First, eye movements occurred as if the animal were looking around, then the ears and the limbs moved, and finally the animal suddenly "woke up," sat in a normal position, and ate voraciously any *food* within reach Within fifteen seconds of "waking up" an animal can leap across a gap of three feet between a table and its cage, and catch the cage bars in a completely normal way, *thus demonstrating perfect* oculomotor coordination and control of movement After about six hours, some of the reserpine signs, such as the clenched feet and the fœtal position, reappear, and the monkey's motor activity is depressed, but with only one exception the animals roused themselves when they were offered food This partial return of "reserpine syndrome" is completely abolished by a further subcutaneous injection of 10 mg (0 5 ml) of ritalin—i e, half the previous dose

So dramatic is the *effect of ritalin* that there is little doubt that in these animals it acts as an antagonist to reserpine

Our observation that the completely abolished "reserpine *syndrome*" *tends to build up again*, though to a lesser degree, about six hours after the administration of ritalin suggests that this drug does not "neutralise" nor "wash out" the reserpine

Bein et al[2] *suggest that the action* of reserpine resembles the effects of diencephalic stimulation, and they conclude from their observation of the cat's retracted nictitating membrane that reserpine inhibits the sympathetic *outflow and does not stimulate the* parasympathetic component of the hypothalamus A syndrome similar to that observed by us after a large dose of reserpine has been reported in monkeys by Collins[3] *following* lesions in the posterior hypothalamus reaching into the rostral portion of the midbrain Hess[4] also observed in cats with mid-hypothalamic lesions a type of behaviour, "adynamia," which closely resembles what we have observed in monkeys

We therefore assume that reserpine acts at hypothalamic level, favouring the parasympathetic centres either by stimulating them or by depressing the sympathetic centres *The antagonistic effect of ritalin* could then be the result either of removal of this depressant effect or of increase in the sympathetic output of the hypothalamus, thus in either case re establishing a balanced hypothalamic function

The effects fo amphetamine and bemegride administered after reserpine are also being investigated The effects of amphetamine closely resemble those of ritalin, with the addition of increased motor activity The effects of bemegride are very different

We thank Prof E G T Liddell for his support, Dr C D Falconer for his interest in this work, and Ciba Ltd for supplying 'Serpasil' and 'Ritalin'

Letters to the Editor

Visiting in Mental Hospitals—Today there is some talk of improved facilities for those who visit patients in general hospitals, but though in their evidence to the Royal Commission the representatives of the Royal Medico Psychological Association claimed that progress had also been made in mental hospitals, the lack of imagination shown by some medical superintendents is regrettable

Whether a patient in a general hospital receives visits from friends and relatives is, *comparatively, immaterial*, for he is conscious of his condition and aware of his surroundings But for the mental patient—because of the disturbance of judgment wrought by his illness, and his consequent inability to appreciate his predicament—unrestricted visits from friends and relatives are essential He finds himself suddenly, and perhaps violently, uprooted from everyday life, and cast into the confusion and indignity of a mental hospital ward—there to wage unequal combat with the unspoken suggestion that he *has done something* that he *ought* not to have done, and to regard himself as the object of an accusation, against which he is required to defend himself Realising that something has occurred to set him apart from other men, he instinctively gropes for that sympathy and understanding which must come first from his friends and relatives, *and secondly* from psychiatry Unhappily, however, and all too often, his grasp closes on thin air, for, though half our mental hospitals wisely permit visitors at any reasonable hour on any and every day, the rest limit visits to certain days and specified times

Cortisone versus Aspirin

IN early rheumatoid arthritis cortisone relieves symptoms no more effectively than aspirin This conclusion, recalled some weeks ago by Dr BAYLISS,[1] was the utcome of a carefully controlled trial conducted by the Medical Research Council and the Nuffield Foundation[2] The investigation was confined to early cases, and to many it seemed possible that this group, in which a high proportion of spontaneous remissions was to be expected was not best calculated to reveal any difference between the two methods of treatment Accordingly the Empire Rheumatism Council designed a comparison of the same two drugs in patients with disease of varying duration—selected only in so far that anatomical changes were not too advanced to preclude measurable improvement in function A novel feature of this trial, the first results of which have now been reported,[3] was an attempt to assess the progress of changes in the radiographic appearances of the joints Nine centres contributed patients, who were allocated centrally and at random to the two treatment groups In the cortisone group treatment started with a total daily dose of 75 mg, and the dose was later adjusted to the smallest which would keep the patient largely free from symptoms To avoid the dangers of high dosage it was decided that treatment with cortisone should be abandoned if symptoms could be controlled only by a daily dose as great as 100 mg The absence of serious complications is probably due to this precaution, and to the exclusion from the trial of patients with gastric disease mental instability, or hypertension At the end of a year (the trial is to continue for three years in all) there was no significant difference between the two groups in functional capacity, number of joints affected, hæmoglobin value, erythrocyte sedimentation rate, or progress of lesions demonstrated radiographically In the cortisone group the mean sedimentation-rate was normal at the end of the first and second months (thus differing very distinctly from the aspirin cases), but the rate then rose rapidly, and from the fifth month there was no difference between the two groups, in each of which the mean rate slowly fell till the end of the year Hæmoglobin values were higher on the average in the cortisone group at the end of six months, but after a year this difference too had disappeared Serial radiographs, which were inspected particularly for the development or enlargement of juxta articular erosions in the wrists and hands, gave a hint of greater deterioration in the aspirin group, but statistically the difference was not quite significant

Thus in rheumatoid arthritis of varying duration, as in early cases (as well as in rheumatic fever[4]), salicylate or aspirin emerges from the rigours of controlled comparison in no way inferior to cortisone The crucial question whether either drug fundamentally alters the progress of the disease remains unanswered Ethically it would be unjustifiable to withhold all treatment from a control group of patients, but some information might be gleaned from a comparison of treatment with large amounts of aspirin and with minimal analgesic doses Meanwhile, the evidence from this and earlier trials raises the question whether cortisone, with its acknowledged dangers, is ever indicated in rheumatoid arthritis As regards prolonged administration in largely unselected cases, the Empire Rheumatism Council investigation (at any rate at the stage of this first annual stocktaking) gives an answer as unequivocally negative as did the previous investigation of early cases Are there any situations, or is there any special group of cases, in which the potent effects of a short course of cortisone can be beneficial? BAYLISS[1] believes that such courses may sometimes help in reablement—an effect which is not easily proved—and in some acute febrile cases If it could be shown that cortisone diminishes the damage to joints, which advances rapidly in some of these cases, its use during the active phase, which is often short, would certainly be correct In severe and unrelentingly progressive cases the temptation to try cortisone is great, but there is no good evidence that it improves the outcome The second and third years of the Empire Rheumatism Council's trial may produce different conclusions, but this seems unlikely and clinicians will be more anxious to hear how prednisone and prednisolone have fared under similar conditions of test

Clinical trials of this sort have become a necessary accompaniment to the introduction of new and potent drugs The comparison of corticotrophin, cortisone, and aspirin in the treatment of rheumatic fever, sponsored by the Medical Research Council and the American Heart Association[4] was a notable instance of international collaboration in this field Prompted by this trial, the American Rheumatism Association considered the feasibility of a similar study in rheumatoid arthritis, but as a preliminary it undertook a retrospective analysis of the experience of several clinics with cortisone in rheumatoid arthritis—a study which necessarily did not include a control group of patients[5] The limitations of this type of survey were recognised by its organisers, and have been analysed by MAINLAND[6] The difficulties are exemplified by the wide range of results reported by different clinics the proportion of satisfactory results after a year of treatment with cortisone ranged from nil to 70% Nevertheless some useful facts were collected The major undesirable effects in 314 patients who received more than 50 mg of cortisone daily included pathological fractures in 5 1%, psychosis in 2 5%, peptic ulcer in 8 3%, and infection in 13 4% In patients with psoriasis and arthritis the skin condition did not seem to be influenced by cortisone Recognition of the direct relation of dosage to undesirable effects has led to increasing caution At a meeting of the American Rheumatism Association last year Dr HOWARD F POLLEY,[7] speaking of experience at the Mayo Clinic, set the highest tolerated maintenance dose of cortisone at 25–30 mg daily for postmenopausal women, 35–40 mg for premenopausal women, and 40–50 mg for men It was pointed out at the same meeting that with doses of this order output of endogenous hydrocortisone

etter to allow pneumoconiotics to continue to work at he coalface if they want to, while keeping them under edical supervision Every effort should of course be ade to get rid of dust from the air in the mines

In a Medical Research Council report[5] just published, ILSON and HUGH-JONES record their investigations at he M R C Pneumoconiosis Research Unit in South ales Among their important results (to which we ope to refer in more detail in a later issue), they find hat "it is a man's age rather than the radiological egree of simple pneumoconiosis which is important in redicting his disability" Miners with no radiological neumoconiosis were, on the average, as breathless or their age as men with simple pneumoconiosis and more breathless than non-miners, especially in the elderly, "this suggests," GILSON and HUGH-JONES add, "that such miners might logically receive benefit for their disability"

Annotations

TREATMENT OF EPILEPSY WITH ACETAZOLAMIDE

IN a recent annotation[6] we discussed the effect of carbonic-anhydrase inhibition on electrically induced convulsions in mice[7] Lombroso and his colleagues from Harvard now describe[8] their experience with acetazolamide given to 126 young epileptics during the past three years Results were good or excellent in half their patients, and improvement was maintained for from three to thirty six months No patients deteriorated when acetazolamide was added to or substituted for previous treatment, and in a quarter of all cases the seizures were completely abolished These results were achieved with doses of about 500 mg or 750 mg daily Side effects were not troublesome and there were no serious toxic effects No striking difference was found in the response of different types of epilepsy, though results were rather better in patients with mixed types of seizures (usually a combination of grand mal and petit mal) than in those with petit mal alone, or with other seizure patterns alone Electroencephalographic analysis of the response indicated that results were best in patients who showed much spike wave activity, especially when hyperpnoea induced slowing of the waves and profuse spike wave discharges In such patients acetazolamide sometimes restored the E E G pattern to normal

In a letter in our issue of Feb 25 Professor Golla and Dr Sessions Hodge reported that they had added acetazolamide to the treatment of 70 patients suffering from petit mal The seizures were completely abolished in 25 of these patients during the first month of therapy, and only 2 of the 70 failed to show some improvement Professor Golla and Dr Sessions Hodge have not so far assessed the action of acetazolamide in major epilepsy

Like other drugs used in the treatment of epilepsy acetazolamide has apparently caused agranulocytosis[9], and thrombocytopenia[10] and renal lesions of sulphonamide type[11] have also been reported There may be other serious disadvantages in the prolonged inhibition of an enzyme so widely distributed as carbonic anhydrase But that does not mean that acetazolamide may not prove to be an important addition to the treatment of epilepsy

THE CHALLENGE OF MENTAL ILLNESS

THE Ford Foundation has given £75,000 to be spent over the next six years by the Mental Health Research Fund, which was founded four years ago by a group who believe that mental health and mental illness have not had the share of research which their immense importance demands[12] The tasks the Fund has set itself are to establish research fellowships, to encourage coöperation between workers in different fields, to support specific investigations, and to assist exchange of information, and the cost of the commitments it is now contemplating will be not less than £23,000 At its annual meeting on March 6 the chairman, Mr Ian Henderson, pointed out that through this Fund the friends and relatives of the mentally ill can give effective expression to their desire to help Sir Russell Brain spoke of the achievements of other voluntary agencies, such as the British Empire Cancer Campaign and the Empire Rheumatism Council, and said that these unofficial sevices are needed today every bit as much as in the past, when they so often led the way No money could be better spent, said Dr William Saigant, than that spent on the relief of intolerable mental suffering

RESTRICTION OF ANTIBIOTICS

ON Jan 28 and March 3 we discussed measures taken by the New Zealand government to conserve erythromycin for use only in infections resistant to all other antibiotics We said that from Feb 1 New Zealand doctors would be able to get erythromycin only through hospitals and only for the treatment of diseases which did not respond to other remedies This restriction applies to erythromycin supplied at the cost of the Social Security Fund, but not to other prescriptions for the drug We are indebted to Mr J R Hanan, New Zealand minister of health, for pointing out to us that the restriction is more limited than we supposed from the reports reaching us This important decision was however, based on the considerations we set out in our leading article of Jan 28, and, in reply to a point we raised, Mr Hanan adds that New Zealand hospitals have in fact been advised to go very carefully in their own use of erythromycin

CERVICAL LUNG HERNIA

HERNIATION of the lung is rare in 1946 Maurer and Blades[1] found 185 cases on record, and they were able to add only a few more The site of the hernia is variable, but most recent reports[2–11] have described cervical hernias, and Fenichel and Epstein[12] now suggest that this variety is commoner than the small number of reports would suggest, for in a short period they saw 19 patients with this condition Sometimes trauma or developmental defects have clearly been responsible, but Fenichel and Epstein consider that in their series the important cause was the strain of frequent coughing Their patients were elderly and they had all had coughs for years except 4 who, however, had emphysema like most of the others In 5 cases, there was a persistent, soft, resonant, supraclavicular swelling which distended on coughing, in the others, the bulging appeared only on coughing Usually the herniation was bilateral

The apex of the lung normally rises 2–5 cm above the level of the first costal cartilage, and expansion upwards and medially is limited by the pleura and the deep cervical fascia (Sibson's fascia) During the expiratory phase of coughing, when the contraction of the thoracic and abdominal muscles tends to thrust the apex of the lung further through the thoracic inlet, the pressure on Sibson's fascia must be considerable, and Fenichel and Epstein believe that in some patients with chronic cough the fascia may become so stretched and lax that the lung can bulge into the neck They think that emphysema may be another cause, because it tends to produce an upward tilting of the first rib with consequent widening of the thoracic inlet Supraclavicular bulging in emphysematous patients is probably well recognised, but it is not usually described as lung herniation In diagnosis, Fenichel and Epstein found that a lateral radiograph of the neck was of value In normal short necked people with heavy chests the cupola of the lung could not usually be seen, but it was visible in long lean individuals and also in patients with lung hernia In normal subjects, however, even when the apex of the lung could be seen in the neck at

It might be the result of the direct stimulus of the original infecting bacilli, or of dead bacilli, or of the growth of attenuated resistant bacilli present in small numbers in this inoculum, or of the growth, during the four weeks before the second challenge, of a few sensitive bacilli that survived treatment with isoniazid The number of bacilli in the initial challenge, however, was very much larger than would be expected in human infections, and none of these mechanisms would be likely when the infecting dose was smaller Thus, this experiment did not exclude the possibility that prophylactic isoniazid might hamper the development of immunity after an infection on the scale to be expected in man Though isoniazid might actually prevent the development of immunity, it would still succeed prophylactically if it killed all the bacilli, but there is evidence[2] that in mice infected with many bacilli isoniazid does not eliminate them all, though the number of organisms in the animal's tissues is much reduced One might suppose that, in infections with small numbers of bacilli, all the organisms would be killed, but there is no definite experimental evidence on this point Finally, it may be that the free use of isoniazid alone would encourage the emergence of resistant strains This seems unlik since the infecting dose of bacilli responsible for human tuberculosis would be small and would ver dom contain any of the rare resistant mutants that a present in sensitive strains

Much experimental and clinical evidence, includ the recent Medical Research Council trial,[3] has shown th B C G vaccination can provide a useful degree of immun —but not complete immunity Isoniazid, on the ot hand, apparently provided complete protection during period of treatment in the guineapigs Thus isoniaz *during the time it is given*, may be better than B C G, b later there may still be risks from lack of immunity a the occasional persistence of tubercle bacilli in the tis Nevertheless, B C G vaccination and prophylactic i azid might be combined with advantage For examp CANETTI[4] has suggested that isoniazid might be given a the same time as vaccination with an isoniazid re istar variant of B C G, thus combining considerable immedia protection with a lasting immunity Further anim experiments will enable us to judge these importa possibilities more fully

RESPONSIBILITY EVADED

THE growing disposition of patients to seek legal remedies for supposed medical negligence has caused hospitals to re examine their practices, and, where such revision abates the grounds for action, this will usually be to the advantage of both hospital and patient But the enhanced risk of actions should not lead hospitals to evade their own responsibilities Some months ago a patient who was to undergo "cold" appendicectomy received, with notification of the date when a bed would be free, the following notice

> There has been an outbreak of staphylococcal infection at the —— General Hospital
>
> *The outbreak is responding to the measures taken by the Hospital* Management Committee to limit the spread of infection However, it is felt that, where practicable patients should be aware before agreeing to come into Hospital that there is some increased risk of infection, and that the measures instituted must remain in force until conditions return to normal
>
> I have read the statement above and agree to enter the Hospital
>
> Signed

A patient receiving such a notice might take it to his own doctor, but the doctor could hardly advise the patient unless the hospital had informed him fully about the outbreak, and, even if he could give authoritative advice, this would not still the patient's uneasiness at such a chilly gesture from the place to which he looked for help Surely the hospital's duty was to obtain, possibly through the medical staff committee, the opinion of those best qualified to assess the outbreak, including the surgeons, the pathologist, and (we hope) the medical officer of health If, then, it had been decided that admissions for "cold" surgery should be continued, this course should have been followed with no word to the patient To require a patient to make up his own mind on an epidemiological issue is no way to retain confidence in the hospital service, and to call for his signature on an ill comprehended legalistic form is more likely to promote than to allay litigiousness

RABIES VACCINE

ONE of the disadvantages in using *animals for the* propagation of virus for rabies vaccine is the danger of allergic encephalomyelitis due to brain antigens in the vaccine It is of some interest therefore to study laboratory and clinical *tests*[1] *of vaccines made from* virus propagated on embryonated duck eggs The resulting vaccine was potent in animal tests and effectively evoked antibodies in humans Local reactions were mild and no systemic effects or neurological signs were found Hence it seems that vaccine made from virus propagated in embryonated duck eggs could often replace that produced in animal brains Since cross sensitivity may occur persons sensitive to hen egg albumen should not be given duck *embryo vaccine*

TUBERCULOUS MENINGITIS OF SUDDEN ONSET

THE onset of tuberculous meningitis is nearly always in dious, but, now and then, the disease begins abruptly Taylo Smith, and Vollum[1] recorded an acute onset in about 4% of their large series of cases The abrupt onset is associated with three other features a tendency to spontaneous remission of *symptoms early in the disease*, *unusually high* cell counts in the cerebrospinal fluid obtained at diagnostic lumbar puncture, and a good clinical prognosis in the treated case

Diagnosis in such cases is difficult The illnesses in the Oxford series mimed, sometimes remarkably closely, a wide range of conditions subarachnoid hæmorrhage, poliomyelitis, intra cranial hæmorrhage, brain abscess, frontal sinusitis, hysteria, and benign choriolymphocytic meningitis The spontaneous remission of symptoms after an abrupt onset is a particularly disagreeable trick of the disease, for, as Trousseau pointed out in 1867,[2] it tempts the physician to change his first opinion —and that may be disastrous The Oxford workers described a case in which the remission of symptoms led them to change their diagnosis from tuberculous meningitis to *benign* choriolymphocytic meningitis They withheld chemotherapy until the diagnosis became unequivocal, and during these crucial days their patient received, it seems, permanent cerebral damage

The unusual clinical course is associated with an anomalous pleocytosis in the C S F The usual range of the cell count in the classical illness is 25 to 500 cells per c mm When the onset is abrupt, the count is uniformly higher, ranging from 500 to 1600 per c mm Smith and her colleagues have shown that intrathecal injection of a large dose of old tuberculin (P P D) generates in a tuberculin sensitive recipient clinical and C S F changes closely similar to those found in the abrupt onset type of true meningitis They suggest *that these acute* cases arise when a large caseous focus suddenly ruptures and floods the C S F with tuberculin loaded material, thus provoking a brisk intrathecal tuberculin reaction This antibody antigen reaction leads to the C S F *changes and* the clinical signs The reaction then subsides and the illness abates Bacteria have, however, seeded themselves within the subarachnoid system, they multiply, their lesions caseate, and finally *the march of the disease* continues

During the past six years Smith and her colleagues have done a great deal of work on the intrathecal tuberculin reaction Their results consistently point to one main conclusion

considerable, proportion of myocarditis was found when inoculated rabbits were placed in a bell jar in which part of the oxygen was replaced by nitrogen

It was concluded that anoxæmia predisposes to myocardial infection by certain viruses This view is supported by the distribution of lesions in relation to the distribution of the coronary arteries In man interstitial myocarditis has often been noted in poliomyelitis Teloh [7] confirmed previous observations [8] that the prevalence of myocarditis varied considerably in different poliomyelitis epidemics suggesting that some strains of the virus were more prone to attack the heart than others Of special interest are the cases in which acute interstitial myocarditis was the only or main manifestation of a virus infection as illustrated in a recent report from Johannesburg [9] While they were in a maternity home or shortly after they had left it 10 infants became severely ill and 6 died The features of the illness were tachycardia cyanosis fever, tachypnœa and toxæmia Some of the babies had a relapsing type of fever like that seen in Bornholm disease Necropsy including microscopical examination was carried out in 3 cases Focal interstitial myocarditis was found in all 3, and in 1 case there was also a focus of encephalitis Thorough virus investigations including inoculation of young mice were performed in 4 patients of whom 1 recovered In all 4 infection with Coxsackie virus (group B) was proved

CLAIM FOR BETTERMENT

On March 7 the Negotiating Committee which is to negotiate the claim for increased betterment for general practitioners and hospital medical staffs gave preliminary consideration to the preparation of the joint claim and authorised the use of the services of counsel in the drafting of the statement of claim It decided that the representation of the public health medical service on the committee should be increased by including two additional members to be nominated by the Public Health Committee of the British Medical Association The present membership is

Prof Ian Aird F R C S Sir Russell Brain P R C P Sir Harold Boldero, F R C P, Dr J D S Cameron Dr T Rowland Hill Mr Charles Read, P R C O G, and Mr T Holmes Sellers F R C S (representing the Joint Consultants Committee) Dr A Beauchamp Dr Guy Dain Dr A B Davies Dr F Gray Dr Talbot Rogers Dr C J Swanson and Dr S Wand (representing the General Medical Services Committee) and Dr J B Tilley (representing the Public Health Committee of the B M A) Sir Russell Brain and Dr Talbot Rogers preside at alternate meetings

Those present included Mr R G D Allen professor of statistics in the University of London and Mr N Leigh Taylor, solicitor to the B.M.A

GAMMA-GLOBULIN

GAMMA GLOBULIN prepared from pooled plasma from healthy adults is distributed through laboratories of the Public Health Laboratory Service for the protection of susceptible contacts of measles rubella and poliomyelitis as follows (see *Mon Bull Minist Hlth Lab Serv* 1956 15, 27)

Measles —(1) For control of hospital and institutional outbreaks (2) For persons with intercurrent illnesses or living in a poor environment for whom measles would be dangerous (3) For attenuation in children under 3 years of age

Rubella —For women exposed to infection in the first four months of pregnancy

Poliomyelitis —(1) For nurses and medical students closely associated with the care of early cases who have not been in known contact with the infection (2) For babies in a hospital or maternity home exposed to infection soon after birth (3) For children in a hospital ward where a case has developed—especially children who have recently undergone tonsillectomy

In addition gamma globulin prepared from the blood of persons recently vaccinated against smallpox is held for the treatment of generalised vaccinia or accidental vaccinial infections endangering the eye, and, in special circumstances for the protection of unvaccinated smallpox contacts

The Widdicombe File

XXXI—TOO LITTLE—AND LATE

DEAR HAWKE,

Mrs Neal has just gone out again This time she stayed in hospital for over two weeks, she had seven pints of blood, and her hæmoglobin rose from 34% to 65%

You may have good cause for satisfaction When somebody has had forty three pints of blood the uneventful transfusion of a further seven is an achievement on which the pathologist can justly look with pride Thanks to you and your colleagues a blood transfusion is probably the simplest and safest life saving operation in the whole of medicine The meticulous care taken in the collecting and in your grouping and matching, is almost enough to eliminate hazards at your end when the occasional mishap does occur, we all know that we must first look for the cause in ourselves Even the blood of Mrs Neal, with its antibodies and its hyperglobulins, is a poor challenge to your resourcefulness Your modest labels reading "Compatible Washed Cells do not deceive me as to the vast amount of work they conceal Mrs Neal has had her sixteenth transfusion without batting an eyelid

Yes you may well be satisfied But as her physician, I am not Seven pints is a lot of blood, but 65% is a long way from 100%, and two weeks is a long time

I have worked out that for her sixteen transfusions Mrs Neal has spent a total of close on five months in hospital Members of the committee might well throw up their hands in horror and weep over the £19 odd that it costs to maintain one bed in our hospital for one week but far more important considerations are at stake Often we have been very short of beds and have had to refuse admissions because Mrs Neal was taking up a bed For a time we tried taking her in when the blood was ready but you never sent enough and she still had to wait another week for the second instalment We tried giving her a few surreptitious bottles from our emergency stock but you found out and made a fuss We persuaded her relations to become donors but it has made no difference

Of course Mrs Neal is no less anxious to get out of hospital than we are to expedite her return home Last summer we tried to top her up for her summer holiday but you could not spare the blood in time We had to keep her in over Christmas for the same reason Your explanation for the delay is always the same Group O Rh negative blood is precious and the demand is heavy The need is more urgent elsewhere Sometimes there is an exchange transfusion for rhesus incompatibility and this must come first

So you see, this problem goes deeper and deeper, until it reaches our fundamental medical and other principles Is the life of this patient whose aplastic marrow renders her dependent on the blood of others any more or any less important than that of a jaundiced newborn babe? Are we to set ourselves up in judgment and say This life is worth preserving but that *one* is not "?

Mrs Neal is a simple soul She does not know what is wrong with her and would not understand if we told her She has no special gifts and her education leaves much to be desired. She has no hobbies and would be hard pressed to say what she does with herself all day At 60 she feels she has earned a rest and therefore lets the younger members of the family attend to the work Not that she appreciates her family any more than she appreciates all the medical attention she is having It would certainly never occur to her that fifty donors have given their blood freely to keep her alive for a year Instead she nurses a deep resentment against all of us because we cannot cure her at less inconvenience to herself Her simple mind cannot understand why she has to have transfusions when her friends and neighbours are revived by a few iron or vitamin pills

Many would say, here is a worthless life if ever Society could suffer no loss by her untimely end Her relations may well feel relieved of their burden A hospital bed would be freed

One can argue that when a man is struggling in the final stages of some fatal disease it is kindness to let him die peacefully There comes a time when penicillin may thoughtlessly deprive some age wracked body of its last friend It is as well if the infant imbecile need never open its eyes upon a cruel world

In all this I confess my guilt, but I cannot place Mrs. Neal in the same category Are you going to abandon someone who openly demands life as her birthright? Are you who hold the elixir of life, prepared to accept this terrible responsibility?

and the instructors, and the subjects of discussion include absenteeism, lateness, difficulties with authority, and relations within the group. Present working problems are related to outside factory problems and this trial period allows the patients to analyse their attitude to work. One of the patients acts as secretary and each group reports back to the community meeting which all patients and staff attend. The work groups have come to take a new pride in their work, and their group consciousness has grown. They now assume responsibility for the absentee, the isolate, or the bad worker, and try to help him to understand the meaning of his antisocial behaviour and to work better. Pay is seldom discussed and is apparently not considered necessary.

AN APPROACH TO REAL LIFE

Work therapy, because it approaches real life, presents different problems for women than for men, since their social rôles outside the hospital are different. At first we encouraged the women to go to the handicraft shop, work in the needleroom, and help with the housework of the unit, and we organised discussion groups on infant care, beauty culture, and so on. Our ideas, however, were based on the middle class habits familiar to most of the staff, and here again we seemed to have paid too little attention to the patients' own views on their needs and their probable future. When we came to discuss this topic with the women patients themselves, we became aware of our ignorance of their place in society. Because of their personality difficulties many of the women patients of a unit such as ours do not expect to achieve the ordinary social goals. Marrying, having children, or even housekeeping may be difficult for the majority. Instead they will probably work in some relatively unskilled capacity, often alongside men, and live in relative isolation in one room. They expressed a wish to work with the men in the workshops, and when this was put into practice, most of them seemed to be much more interested than they had been in their previous occupation. Moreover, their presence was welcomed by the men.

In this way, handicrafts have ceased to exist as a female occupation in the unit. This change clearly shows one difference between occupation therapy (handicrafts) and work therapy. Many occupational therapy departments give much help to the more ill or dependent patients, but, when rehabilitation has reached the stage of preparing them for ordinary work, a group task involving production work of social value is to be preferred to individual tasks carried out in relative isolation in a handicrafts department. It is not enough to get patients to do something: they must be helped to identify themselves with the staff and the ward environment and given some choice in what they want to do. If the staff are willing and able to identify themselves with the patients a shared task and a social experience can be therapeutic.

PERMANENT SHELTER

Many patients, remaining in hospital, continue to work in laundry, farm, and so on for most of their lives. Ideally the same care should be taken over their placement and working conditions as is aimed at in the resettlement of patients in open employment. Work incentives, hours of work, and social conditions, will depend on the particular circumstances of the hospital, but there seems to be no serious objection to the establishment of a sheltered factory in or near a mental hospital, preferably under outside management, to which suitable cases could be referred.

Where the patient, though discharged from hospital, has a severe physical or mental disability, the sheltered workshop will often be the right solution. Britain is fortunate in having probably the best organisation to be found anywhere for the rehabilitation and resettlement of disabled persons in either open or shelter employment, and for this the Ministry of Labour a National Service deserve the main credit. Unfortunately, these services are too little known by doctors generally and it is a pity that the official booklet[1] is not mo widely read.

We should like to thank Dr. Louis Minski, physician superintendent of Belmont Hospital for his support. Also Mr. C. Brooks, Mr. F. Jaquest, Nurse P. Mateer, Mr. J. Sm and Mr. E. Taylor who have the major responsibility f the five work groups described in this paper. Dr. R. Rapop has given us much needed advice from the social point of view.

Before Our Time

DEATH UNDER CHARLES II

WHAT did our ancestors die of? Burial registers so seldom give any details that it is interesting to quote a rare exception.

For ten years from Oct. 14, 1653, to Nov. 28, 1663, the burial register of St. Michael's Church, Cornhill gives us the cause of death for most of the 250 people who died in that parish and were buried there. Starting with Michaell Earnley, a linendraper who died of a "feaver" on Oct. 14, 1653, we have on Nov. 10 John Turner "overlay'd" and Jane Hutcheson and Edward Paine who died on the 12th and 13th respectively of "ricketts" and "convultion." Analysing the detail for the ten years we find "consumption," usually spelt with two "s's," in the lead with 30 cases over "feaver" (unspecified) with 28. Smallpox accounts for 16 deaths and "aged" for 13. Infant mortality is deplorable. There are 12 deaths each from "teeth" and "convultions," 8 from "ricketts," and 4 from "thrush," with another unfortunate child who had "black thrush," whatever this may be. Yet "measles" causes only 3 deaths in the whole period. Amongst adults 4 died of "stoping of the stomack" and Mary Tomlinson, a widow, in March, 1662, of "timpany," which sounds like a musical instrument but is probably much the same thing. On the other hand, 6 people died of "scowring," whether therapeutic or not is unstated. Mrs. Elizabeth Payer, a doctor's wife, died on March 28, 1654, of "travell," and Elizabeth Golling, a barber's wife, of "griefe." There are 2 cases of murder and also a servant, Robert Butler, who was "casually shott." 4 women died from "childbed," and 2 sportsmen, Robert Brooks a merchant tailor, and Joseph Bannister an upholder (? upholsterer), from "surfetts." Kidney disease and "stone" account for 3 deaths and "dropsey" for 7 more. Only 1 case of "cancer" occurs in the series, but we have 2 from "palsy" and 1 from "gangrene" together with 2 each from "scurvey" and "jaundies."

Amongst other odd entries is that of John Smith, a hotpresser, who died of "tissick," which is rather baffling until we find a child, Jane Boyle, with the same complaint—almost certainly whooping cough. Three people died of "flox," which apart from the obvious misspelling has me puzzled, and the long list concludes with an anonymous maidservant of one John Harris a linendraper, who fell downstairs on Nov. 28, 1663—apparently the only fatal accident in the home or the streets throughout the entire period.

A comparison between this list and a cross section of a parish register in these days should prove extremely interesting, if only to note startling changes in our time.

Remuneration of Doctors —It would be interesting to know the family status of those doctors who advise restraint in the matter of salaries To mention one financial problem alone—the fees at a public school famous for its medical affiliation amount to nearly £300 a year Those of us with three or more children find it impossible to contemplate such an outlay, even for one child

There is a large number of competent specialists in this country who have seen their share of war service and junior appointments, and who are making their contribution, in research and published work, to the widening of our professional frontiers Many of these are forced to take up S H M O appointments because of the paucity of consultant vacancies Their starting salary 12–14 years after qualifying is £1500 a year with an increment of £50

Could our more fortunate colleagues tell us whose children are entitled to these educational facilities if not our own ?—
M D , M.R C P

Obituary

Professor SAMSON WRIGHT

For 30 of his 57 years, Samson Wright's name was identified with his *Applied Physiology*, and up to the day of his death last Sunday he was working on its 10th edition. This famous book, which is said to be as much read in America as here, arose out of the courses for the primary F R C.S examination held at Middlesex Hospital where Wright had become assistant to the late Prof Swale Vincent soon after graduating M.B with the gold medal in 1922, and where (after an interlude at King s College) he has been Astor professor of physiology since 1930 In person and with the pen, he was a fine expositor, and a teacher who increased his pupils' wish to learn One reason for this was that his interest in medicine was by no means confined to his laboratory, and his interest in life by no means confined to medicine Deeply concerned by the distress of the Jews in Europe under Nazi regimes, he made himself a powerful helper and champion of our German and Austrian colleagues who escaped to this country, and latterly he has been one of the most useful British friends of the Hebrew University of Jerusalem, where a laboratory has been named after him If often critical he was direct, friendly, and sincere. Few men of our generation have taught so many so much and so well

Surgeon Captain W I GERRARD

Captain Gerrard, who died at his Aberdeenshire home on March 7, formerly held the chair of medicine at Hong-Kong After graduating at Aberdeen in 1909 he joined the medical inspectorate of schools During the 1914–18 war he served with the R N V R and he afterwards joined the R N Medical Service On retiring from the Navy he was appointed professor of medicine at Hong-Kong and physician to the government civil hospital He was elected F R C.P in 1936, and was appointed O.B.E For his services in the Navy during the late war he was promoted C B.E

News

On March 7 the Confederation of Health Service Employees asked the 10,000 nursing staff in 33 mental hospitals who are unofficially banning overtime work to abandon their action (*Times* March 8) If the negotiations on salary and conditions of work have not progressed satisfactorily the confederation will impose an official ban on May 1

Sir Ernest Finch has been appointed Hunterian orator of the Royal College of Surgeons of England for 1957 Mr R H Franklin and Mr Clifford Jones have been admitted to the court of examiners of the college and Dr Ronald Woolmer reader in anaesthetics at Bristol University, has been appointed director of the department of anaesthetics A diploma of fellowship has been granted to J Sunderman.

The National Institute of Industrial Psychology has awarded the Vernon prize for 1956 to Mr J S Weiner, PH D, honorary assistant director of the Medical Research Council unit at Oxford on climate and working efficiency

Sir Stewart Duke Elder will give the Thomas Young lecture on Thursday April 12 at 6 P M at St George s Hospital, London, S W 1 on the Eyes of Invertebrates

Dr R H M Stewart has been appointed senior administrative medical officer to the Newcastle Regional Hospital Board

Dr A. H Douthwaite will give the Croonian lectures to the Royal College of Physicians of London on Tuesday and Thursday, May 1 and 3 at 5 P M on Pitfalls in Medicine

On March 2 Mr R H Turton the Minister of Health opened a new villa at Fulbourn Hospital Cambridge The villa which is to be used as a social therapy unit will accommodate 40 women patients It contains wards recreation rooms a dining room with tables for four and a fully equipped kitchen

CONTROL OF YAWS

W H O Symposium in Nigeria

THE second W H O International Yaws Symposium was held at Enugu, Eastern Nigeria, on Nov 9–24, and it was attended by 53 participants from 30 countries One reason why this part of the world was chosen for the meeting was because it is the site of a particularly active anti-yaws campaign In the Nsukka Division alone from mid-February, 1954, to mid-May, 1955, no less than 383,769 persons were examined and treated, while in Nigeria as a whole more than 1,100,000 people had been examined by July, 1955

The first W H O symposium on yaws was held in Thailand, at Bangkok, in 1952 when much base line material was considered The various phases of a yaws campaign were then discussed and later it was possible to define certain technical principles to be followed in mass campaigns At Enugu, where much statistical evidence was studied, the soundness of these principles was found to have passed the test of time

The treponematoses include yaws, pinta, and endemic and venereal syphilis, all of which can be effectively treated with penicillin It was clear from the pooled experience of those at the symposium that endemic syphilis is much more general in Africa than had previously been supposed Earlier data had been largely confined to the *njovera* of Southern Rhodesia,[1] the *dichuchwa* of Bechuanaland,[2] certain foci in South[3] and East Africa,[4] the Sudan,[5] Gambia,[6] French Niger territory,[7] and Northern Nigeria[8] Reports at Enugu told of much endemic syphilis in French West Africa and adjoining territories and in areas bordering on the desert

In a yaws campaign it was agreed that the planning stage should take into consideration *all* phases of the campaign, including the consolidation phase and the ultimate integration of the anti-yaws measures into the permanent health structure of the country Unless this was done there was a danger that once yaws had been virtually eliminated, the success might be short-lived

The first essential in a mass campaign against treponematosis, be it yaws or endemic syphilis, is to treat an adequate proportion of the population less than 90% is considered inadequate

For the treatment of clinical cases, single injections of procaine penicillin with aluminium monostearate (P A M) (1 2 mega units for adults and half of this amount for children) have given excellent results from both the clinical and public-health aspects No-one now believes in the treatment of clinical cases only , there is abundant statistical proof that contacts must also be treated (half the dose of P A M for clinical cases is sufficient) to cover latent cases and those in the incubation period The only difference of opinion is in the definition of a contact

Total mass treatment—i e , the treatment of the entire examined population, as was witnessed in Nigeria (all persons without clinical yaws were regarded as contacts) —has been recommended when the prevalence of clinical cases, both infectious and non-infectious, exceeds 10% of the population *Juvenile mass treatment*—i e , the *treatment of clinical cases and all apparently non-infected* children under puberty—has been suggested when the prevalence of clinical cases is between 5 and 10% Finally, *selective mass treatment* has been used in areas where the prevalence of clinical cases is less than 5%, when only known infected persons and household contacts are treated The symposium favoured moving this upwards by discarding selective mass treatment and using total mass treatment more often

The conference was particularly impressed by the f that over 1700 cases of leprosy had been discovered Eastern Nigeria by the simple expedient of appoint a leprosy inspector to the yaws teams undertaking ma treatment A search for leprosy and other diseases be conveniently made during the initial mass treatme survey or during the subsequent re surveys which made every six to twelve months

Particular attention was paid to the possibility reintroduction of infection from outside the treated are This is less likely if the standards of living are sim taneously improved, but standards cannot usually be raised fast enough to prevent re entry of the dise unless it is also checked in adjacent infected areas Th is true not only of areas within a country but of who countries, and even continents. The need for yaw campaigns to develop simultaneously in all affected are is therefore an obvious corollary The conference therefore welcomed enthusiastically the proposal of Med Général Vaucel, of France, calling for an immedia planned offensive to eliminate yaws and other endem treponematoses from the continent of Africa

One way of improving living conditions would be to strengthen rural health services and so bring health education to the people It was realised that endemic syphilis could be revived in a treated area which remained underdeveloped, by the importation of venereal syphil from the towns In the planning of such a campaign therefore, the widespread control of venereal syphilis must also be considered

So far no less than 50 million people have been examined and 15 million treated in the W H O assisted campaigns against the treponematoses Very large numbers have been treated in a very short time in the campaign organised by the Eastern Region of Nigeria with W H O help The prevalence of yaws there has been much reduced and those who went to Enugu were impressed by the new health facilities which had rooted in the rural areas in the wake of the yaws teams If this pattern could be followed in a coordinated way throughout the whole of Africa, success would be certain

In England Now

LAST week Princess Christina of Schleswig Holstein and her entourage attended the Hospitals Rugby Cup final between Guy's and Mary's Later certain newspapers put out the unlikely story that the Princess and her two private secretaries, Mr Hugh Jefferies and Mr Humphrey Bolle, were in fact Guy's students, that the Dowager Countess of Blakeley was the mother of a student, and that Lady Margaret Bland, lady in waiting, was the sister of another student However that may be, the Princess was invited to present the cup, and though she was denied that pleasure since the match was drawn, she and her attendants much enjoyed their visit to Richmond They were told that senior consultants are not always noted for their deference to students or for their gentleness to examination candidates , yet what could have been more graceful, the Princess remarked, than the way in which they surrendered their tea to the guests ? Lady Margaret also commented warmly on the courteous gesture of a distinguished surgeon in the committee box who took his pipe out of his pocket, eyed it ruefully, and then considerately put it back again Some may feel that the Dowager Countess having reached her allotted span, should forgo some of the more lighthearted activities that graced her younger days But that gallant lady is not bound by convention, and as the mother of three doctors, a dentist, and a medical student, all of the same hospital, she was determined not to miss this important occasion Indeed, we may join with the official of the United Hospitals Rugby Football Club in saying that her presence contributed much to the success of the afternoon

Scotland's Lead

INTEGRATION is a beguiling word and we tend perhaps o mistake the repeated utterance of it for its achievement. Since the late war the need for integrating the hospital and general medical services has been voiced again and again, but despite some useful gestures—notably, prompting hospitals to offer part-time appointments to general practitioners—the process has not advanced far. Scotland has now given a new lead. The Department of Health together with the Joint Consultants Committee and the General Medical Services Subcommittee has evolved a plan by which young doctors may divide their training period between hospital and general practice and those who have completed training may continue as part time principals in general practice, spending the rest of their time in a hospital appointment. The training period, lasting two years is to start after the preregistration year or on completion of National Service the trainee will work half-time in hospital as senior house-officer or registrar, and half-time in general practice under the guidance of an experienced doctor.

The merits of this scheme are clear. The clinician who passes his early postgraduate years solely in hospitals equips himself fully for neither specialist nor general practice for a patient withdrawn into hospital from home and work and leisure may betray no more of the stresses which have brought him there than does a tissue section of a biochemical process. Furthermore whereas hitherto many who have found no permanent career in hospital have turned to general practice untrained, and often in the spirit of disgruntled outcasts, under the new scheme such practitioners will approach this alternative work prepared—and perhaps less reluctant. Nor will the scheme be valuable only to the trainees. At present the world of hospital practice is divided from the world of general practice by a lack of links in everyday activities and the trainees going to and fro cannot but bring the two together, to the refreshment of each. Finally, the scheme may mark the start of more coherent care of patients the prevalent disparity in treatment between hospital and general practice is surely due not only to differing resources but also to lack of mutual understanding.

This plan will call for good will between the two branches of the service, and suitable hospital posts are expected at first to be few. But small beginnings are not to be despised.

A New Serotype of Esch Coli

Two recent papers report the identification of *Escherichia coli* type O 128 B 12. TAYLOR and CHARTER[1] of the Salmonella Reference Laboratory at Colindale, describe how this serotype was first isolated from babies ill in Coventry during July, 1953, and ROGERS and his colleagues[2] give an account of the epidemic that this organism caused at the Birmingham Children's Hospital three months later.

A laboratory at a children's hospital has access to material isolated from circumscribed epidemics of infantile gastro-enteritis among a highly susceptible community but such a laboratory rarely has the means to identify all the antigens in a hitherto undescribed *Esch coli* serotype. The reference laboratory, on the other hand may handle specimens from similar epidemics from widely separated areas, and it is therefore in a position not only to make a careful analysis of the organisms but also to suggest when epidemics may be related. The reference laboratory is also in communication with similar laboratories in other countries, and a new serotype can thus be characterised within the internationally accepted classification. The serological classification of *Esch coli* depends on the identification of the somatic, surface and flagella antigens, and it is known that a particular somatic antigen may be associated with more than one type of surface or flagella antigen. Though the detailed serological analysis is not essential in routine investigations it is certainly essential to progress in this particular field. The extremely careful and detailed investigations[1] into the antigenic composition of *Esch coli* type O 128 showed that an unusual combination of antigens was present and it is worth noting that the Coventry and Birmingham strains were the only ones which had the surface (B) as well as the slime antigens they also had the same flagella (H) antigen, which could suggest that these were related outbreaks.

These accounts of *Esch coli* type O 128 lend weight to our recent remark[3] about the valuable help that the reference laboratories give to the hospital bacteriologists in this country we also noted how a similar liaison in the United States had led to the identification of another of the serotypes of *Esch coli* (O 127 B 8)[4,5] which are now considered to cause epidemic infantile gastro-enteritis. It is interesting to compare the methods by which control was established in the epidemics due to *Esch coli* type O 128, in Birmingham and type O 127 in America. The Birmingham workers, who were dealing with an epidemic which attacked babies already ill, closed their affected wards and only readmitted babies after those wards had been emptied and fumigated. It would be hard to prove that closing the wards prevented a more serious or prolonged epidemic in Birmingham, but the epidemic was certainly relatively mild. although the specific serotype was found amongst the babies in two wards. TODD and HALL[6] were the first to show that when babies became excretors of the specific serological types of *Esch coli*, chemoprophylaxis reduced the incidence of gastro-enteritis. When it is not expedient to close a ward or unit, this form of chemotherapy can be valuable, as STULBERG and his colleagues[4] showed. They had to deal with an epidemic amongst babies who were well but premature they continued to admit other premature babies to the unit and they relied on neomycin prophylaxis to limit the epidemic, although sometimes therapy had to be continued for very long periods because of the liability to bacteriological relapse.

Both American and British workers screened their new admissions for the presence of the new pathogenic sero-

t with epithelial cells derived from the wound edges and the an appendages lying in the base of the wound, these cells row underneath the superficial clot and cover the wound ithin four days They then lie on a saucer, and are gradally lifted and brought level with the normal skin surface y a blister of exudate containing glycogen and protein, which ecomes invaded, between the sixth and tenth day after he injury, by round cells, capillaries, and reticulin fibres ew connective tissue is now forming and though the activity f the epithelial cells is still manifest at this stage in the formition of "pseudo" rete pegs epidermal regeneration is about o vane, for very shortly these pegs become separated from he surface and contained in small pearls by the developing onnective tissue The pegs are eliminated after three to six weeks by the connective tissue and the deep epithelium at the se of the wound becomes straight, but at no time does either epithelium or dermis in the donor area regain its original morphology Wounds deep enough to cause loss of dermis behave differently in that classical granulations must form and grow up from the base of the wound before epithelium can regenerate, it therefore seems that the dermis is in some way responsible for the initial invasiveness of epidermal cell in the earlier stages of wound healing just as it ultimately controls and limits it In conformity with the process in the main incision, Gillman et al. find that epithelium invades the track of a skin suture, thus accounting for the punctate scars which remain after removal of skin stitches. these can be avoided by closing skin wounds with adhesive tape, a method which they[2] and Williamson[3] recommend.

Q FEVER

Q (query) fever remains a suitable name for a disease whose natural history is still confused and obscure There can be no doubt that many human infections are derived from direct contact with cattle, sheep, or goats, alive or dead. *Rickettsia burneti* has been isolated from all three species it may be present in their milk or, in enormous numbers, in the products of conception. Infection of man by man is rare but laboratory infection not uncommon So far the likeness to brucellosis in epidemiological habit is close Not every human infection can however be traced with certainty to an animal source Some epidemics among soldiers during the Italian campaign were attributed in retrospect to sleeping in cow byres On the analogy of other rickettsial infections, it has been suspected that the original reservoir of *R burneti* might be in some arthropod. Infected ticks have been found in Australia, Germany, and England but their connection with human infection is not apparent In California (where the disease seems remarkably common) serological evidence of past infection was found, not only in 20% of those engaged in dairying, but in 1% of those who had no personal contact with animals and who drank no raw milk.

In this country blood from 95 out of 4456 donors gave a positive complement-fixation test for *R burneti*, and sporadic infections make up a small but fairly constant proportion of the aggregate of "atypical pneumonia". Many of these cannot be traced in any way at all to the larger domestic animals, while others occur in places where animals are known to be infected but where clear demonstration of the channel of infection is so far wanting A recent small epidemic in Cardiganshire exemplifies this[4] 15 people in three near by villages were infected within a few weeks No common factor was found in food, drink, or personal environment It was the lambing season (and the uterine discharges from an infected animal tend to be heavily charged with *R burneti*) but not all the patients were actively concerned with lambing Of the sheep with which some of the patients had been in contact 3 5% gave some serological evidence of infection but the rickettsia could not be detected in the ewes' milk. A pertinacious inquiry ended with the problem so far unsolved that the investigators suggest some unrecognised source of infection, common to man and animals. Those who see no future in the epidemiological investigation of infectious disease should accept the challenge Ticks are not the only arthropods which plague us and our beasts another rickettsial disease scrub typhus is spread by trombiculid mites Not much attention has been paid to infection in the smaller animals kept as pets. It was suggested long ago that the epidemics in Italy were due to the inhalation of dust containing particles of infected cow dung Knowing that *R prowazeki* will survive for many months in dried louse faeces, this was a most reasonable guess[5] Farm buildings are dusty places and even in this mechanical and tarmacadamed age animal faeces must make up an appreciable part of the road dust inhaled by the countryman every fine day and by his urban visitors at weekends

HIDDEN BENEFITS

Today we are all citizens and taxpayers of the Welfare State Many people feel that these two rôles give them the right to play a third—that of a critic—and they readily offer their views on the administration and scope of the social services

The commonest complaints are that the Welfare State has tried to do too much too quickly, that it has sapped the moral fibre of the nation, and that it has imposed an excessive burden on the middle classes But Prof R M. Titmuss[6] thinks that these objections arise mainly from lack of clearness about the meaning of the term "social service" Such uncertainty is, indeed, excusable, for during the past fifty years the term has been extended from provision for such limited communal needs as poor relief and sanitation to include the universities and public museums Nor has the Treasury, Professor Titmuss admits, made things easier The welfare services which it recognises as social services seem to be chosen haphazard, and its classification has been influenced by administrative convenience rather than similarity of purpose Thus family allowances count as a social service but remission of taxes for children does not, compensation to doctors for the goodwill of their practices counts as a social service but superannuation under an occupational pension scheme does not These two examples of apparently illogical classification are also examples of two large groups of concealed social services which Professor Titmuss describes as fiscal welfare and occupational welfare.

These two often unrecognised groups of social services now cost a lot of money—more perhaps than is generally recognised Thus a father with two children under 15, if he has an income of £2000 a year will receive over the life of the family a "bounty" of £1455 if he has an income of £400 a "bounty" of only £422 Similarly occupational pension schemes cost the Exchequer [7] £100 million a year, which is more than the present Exchequer cost of National Insurance pensions Professor Titmuss holds that, though these fiscal and occupational reliefs have sound and admirable aims—to strengthen the family or to promote good relations in industry—they distort our social services because, by offering greater benefits to the highly paid than to the less well paid, they are "enlarging and consolidating the area of social inequality". The alternative view, of course, is that these tax reliefs do not in fact do enough, in a period of inflation, to mitigate the egalitarian effect of taxes which rise so rapidly with income that (in the words of the Financial Secretary to the Treasury[7]) it has become hard to remunerate adequately men in any walk of life who carry great responsibilities Professor Titmuss's use of the word "bounty" is no doubt technically correct, but to the ordinary taxpayer it sounds a little odd as applied to permission to retain, for socially useful purposes, a little more of one's own money

AFTER MENINGITIS

We have suggested[8] that those who treat meningitis in childern have a duty to follow their patient's progress for many years The early results of treatment may seem better than they really are, for "mental defect is notoriously elusive in early childhood and epilepsy commonly matures silently between the primary insults and the onset of seizures"[9] Desmit,[10] writing from the Hague reports 114 cases treated between 1949 and 1954 The minimum follow-up period was rather short—six months 4 children (2 of whom died) were excluded from the survey Of the remaining 110, 8 died and and 16 were left with gross defects. Thus the least possible failure rate in this series was 22% The figure might well increase if the children were followed for a longer time Desmit points out that convulsions and prolonged coma were common in those with permanent damage, and he suggests that the illness in these children was encephalitic as well as menin-

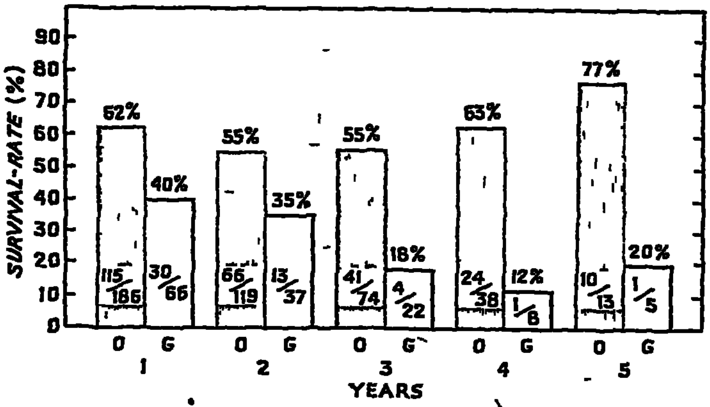

Fig 3—Influence of glandular involvement on survival-rate O = no glandular involvement. G = glandular metastases found

similar to that for patients with squamous cell tumours (43% and 46% respectively)

Influence of Glandular Involvement

The dominant influence of mediastinal-node involvement on prognosis has been stressed by many workers, Bignall and Moon (1955) state that the five year survival-rate of patients without glandular involvement was as high as 48%, whereas in those with glandular involvement the rate was only 11% The proportion of patients found at operation to have glands containing metastases depends largely on the thoroughness of the search for them (H C Nohl, personal communication) In only a few cases in this series was the hilum of the resected lung carefully dissected, nor were sections of all glands examined routinely, yet histological evidence of glandular metastases was found in 70 (27%) cases

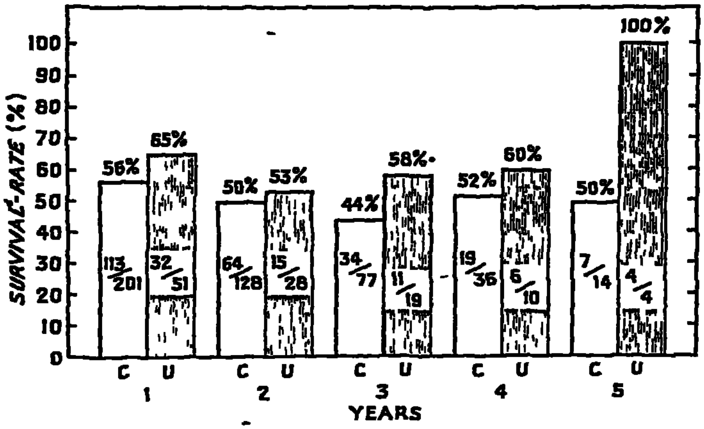

Fig 4—Influence of anatomical type of tumour on survival rate C = circumscribed lesions U = uncircumscribed lesions

Fig 3 compares cases in which no glandular metastases were found with those in which glandular involvement was proved histologically The survival rate after two years was very considerably lower in the latter group (35% as against 54%), and it fell off even more one year later (18% as against 55%) Since only 30% of the patients with glandular involvement eventually died because of local metastases, the finding of malignant glands in a resected specimen probably indicates that the disease is already widespread

Circumscribed and Uncircumscribed Tumours

Both Raeburn and Spencer (1953) and Walter and Pryce (1955) have emphasised that the majority of bronchial carcinomas originate at th periphery There is, however, a clinical entity often described as a "peripheral" carcinoma, the lesion is peculiar in that the greater part of the shadow cast on a radiograph is due to tumour tissue, and that it is far more commonly associated with pulmonary osteo arthropathy than are more centrally placed tumours (Semple and McCluskie 1955) In order to avoid confusion the term "circumscribed," originally used by Rabin and Neuhof (1934), has been applied to these characteristic round lesions They form th greater part (76%) of the present series

There was no significant difference between the proportions of the three cell types in the two groups, but glandular involvement was a littl commoner in the uncircumscribed tumours (31% as against 24%) Fig 4 shows that the "uncircumscribed" tumours had a slightly better prognosis (53%, as against 50%, survived for more than two years) This difference is interesting although probably not significant

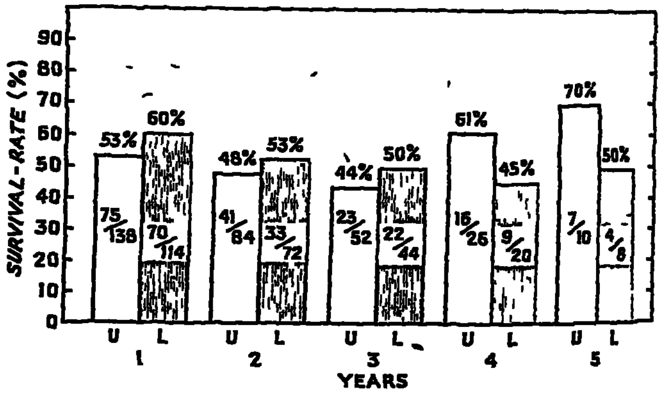

Fig 5—Influence of site on survival rate U = upper-lobe tumours L = lower-lobe tumours

Influence of Site of Tumour

The 264 tumours in this series were evenly distributed throughout the lungs, and there was no difference between the prognosis on the two sides, nor between the upper and the lower lobe (fig 5) In the cases analysed by Bignall and Moon (1955) tumours situated in the left lower lobe were associated with the lowest survival rate, but the majority of the lesions in this series were of the circumscribed type, in which the factor of proximity of the tumour to vital structures influencing operability, and so prognosis, did not come into play

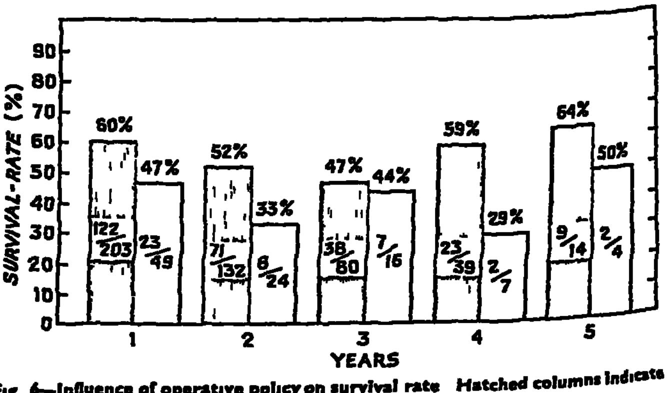

Fig 6—Influence of operative policy on survival rate Hatched columns indicate "policy" resections

Relative to the usage of antibiotics, superinfection this type is extremely rare. But when it occurs it is ten dramatic and disastrous, and constant vigilance therefore required whenever oral antibiotics are used ad particularly when an attempt is being made to erilise the gut. Several authors have remarked that atients look and feel quite well in the early stages of a apidly fatal diarrhoea.[22] In staphylococcal enterocolitis is probable that they remain well until the blood iochemistry becomes upset and possibly also staphylococcal toxin has accumulated to produce toxaemia.[22, 23] At this stage the patient becomes profoundly ill and may die within a matter of hours. The clinical course has been aptly compared with that of cholera. Being so much quicker, bacteriological examination of a slide is preferable to culture of the patient's stools and may more accurately reflect the bowel flora present. Usually one organism predominates. Those most often found are monilia, staphylococci, proteus, and eudomonas.

TREATMENT OF SUPERINFECTION

In staphylococcal cases early recognition is imperative, other organisms are not so rapidly fatal. In a number of reported cases symptoms have quickly resolved on stopping the drug,[3, 26, 27] which is clearly the first essential. When the blood biochemistry has become deranged, urgent and strenuous efforts are required to restore it to normal. The chief needs are for water, sodium, chloride, and potassium—in that order—and intravenous therapy is almost invariably necessary. Depending on the result of bacteriological examination of a smear of the patient's stool specific chemotherapy should be started as soon as possible. With the introduction of new drugs during the past year or two the prospects of success have improved considerably.

CHEMOTHERAPY OF SUPERINFECTION

Proteus.—This organism may be found in up to 0% of normal stools and is usually regarded as nnocuous. It may not be innocuous when it becomes the predominant organism in the bowel.[28] It is notoriously resistant to antibiotics. Some strains are sensitive to oral streptomycin 0.5 g q.i.d. or to neomycin 1.0 g q.i.d.

Pseudomonas pyocyaneus.—Least often guilty of the inister quartet, this organism is usually susceptible to polymyxin B, a bactericidal antibiotic effective against gram negative bacilli. Though originally nephrotoxic and still liable to produce malaise, fever, skin rashes, and pain when given intramuscularly, polymyxin produces no such side-effects when given orally, for it is very poorly absorbed.[29] It may be given as aerosporin 500,000 units every six hours.

Monilia.—*Candida albicans* may be found in 10–20% of normal stools and, after broad spectrum antibiotics in up to 60% of patients, though it rarely does any apparent harm.[30] While it is unlikely that these drugs heighten the virulence of monilia,[4, 31, 32] there have been any reports of both alimentary and generalised oniliasis following the use of broad-spectrum antiiotics. Hitherto this has been an exceedingly difficult condition to treat, but there are now promising reports of the use of diamidines,[33, 34] *p* hydroxybenzoic acid and its esters[31] and fatty acids.[35] Recently a new antifungal antibiotic 'Nystatin' has become available. This is derived from *Streptomyces noursei*, and in vitro it is very effective against fungi and yeasts especially in the dividing phase. It appears to be of considerable value for the treatment[36] or prevention[37] of intestinal moniliasis. Though only a small proportion is absorbed it is said to improve some cases of moniliasis of the skin and genito-urinary tract.[38] Oral dosage is 500,000 units thrice daily or twice this if necessary.

Staphylococcus.—Strains resistant to some or all of the usual antibiotics are found much more often in hospital than among the general public.[39] Staphylococcal enterocolitis, now the most serious of all forms of superinfection, is therefore essentially confined to hospital patients. It usually develops after three to five days of chemotherapy, when the normal bacterial population has been reduced to a minimum and the field is left clear for resistant organisms. Debility is a contributory factor. The best available drug for its treatment is erythromycin, which suppresses staphylococci but permits the return of *Escherichia coli*.[18, 27] The antibacterial spectrum of erythromycin is very similar to that of penicillin but it also affects some rickettsiæ and larger viruses. It is important to reserve it for the treatment of penicillin-resistant organisms or penicillin-sensitised patients. Its indiscriminate use would soon lead to the emergence of erythromycin insensitive staphylococci as resistance to it can develop with great rapidity.[40] It is issued in acid-resistant tablets of 100 mg each. The dose for an infant is 100 mg, for a child 200 mg, and for an adult 300 mg six-hourly. If necessary higher doses may be given as it is tolerated quite well and seldom gives rise to more than minor gastro-intestinal upset.

An alternative is to use neomycin which is a bactericidal antibiotic effective against gram-positive, gram-negative, and acid fast bacilli. It does not show cross-resistance with other antibiotics. Its parenteral use is strictly limited by its toxicity for the kidney and for the ear, but doses of under 0.5 g per day are regarded as safe for short periods.[8] Orally, only about 3% is absorbed and toxic effects of any sort rarely if ever occur.[41, 42] Its advantages are that at the present time it is effective against staphylococci (including those endemic in hospitals) and many strains of proteus and *Pseudomonas pyocyanea*. Resistance to it develops slowly.[43] It is particularly suitable for preoperative preparation of the bowel because it is effective in about twenty-four hours and sterility is maintained for two or three days after operation without further dosage. In a recent paper Rowlands and Scorer[42] found that 1.0 g orally every four hours for six doses sterilised the stools of nearly 30% of their patients. When preceded by 4 × 1 g doses at hourly intervals the proportion rose to 45%. Waisbren[43] also considers neomycin alone satisfactory, but Poth[41] found that on neomycin alone the stools of 10% of patients grew resistant *Aerobacter aerogenes*. He therefore gave 1.5 g of phthalyl sulphathiazole in addition to 1.0 g of neomycin four-hourly for forty eight hours before operation and he regarded this combination as the best available. Unfortunately strains of staphylococci resistant even to neomycin have appeared in America so the problem cannot yet be considered solved.[44]

SUMMARY

Symptoms affecting one or more parts of the alimentary tract often follow administration of antibiotics by mouth. Most are mild and transitory but still troublesome

TABLE II—SURVIVAL OF PATIENTS TWO AND FIVE YEARS AFTER OPERATION, ACCORDING TO PRESENCE OR ABSENCE OF GLANDULAR INVOLVEMENT AT OPERATION

Group	Glands involved		Glands uninvolved	
	2 yr (%)	5 yr (%)	2 yr (%)	5 yr (%)
Bignall and Moon (1955)				
Pneumonectomy	25	16	64	49
Lobectomy	40	25	57	47
Present series				
Lobectomy	35	20	55	77

squamous carcinoma, and possibly bronchogenic spread took place at the time of operation

Discussion

The results of lobectomy in this series are as good as, if not far better than, those reported for pneumonectomy, even without considering the obvious advantages of a lower operative mortality and slighter loss of pulmonary function

It may be argued that the patients were selected when the tumour was early and localised, and before glands were involved, and that accordingly excellent results might be expected Indeed, glandular metastases were found in only 27% of cases, compared with 58% in the series of Bignall and Moon (1955) These workers point out, however, that comparison of the results of lobectomy and pneumonectomy on the basis of the presence or absence of glandular metastases fails to show any difference which would favour the more extensive operation—a conclusion that is borne out by the figures in this series (table II)

It was felt, therefore, that the survival figures for the pneumonectomies done by the same surgeons over the same period as the lobectomies should be collected, in order to establish the total survival for all resections If this was reasonably close to the survival after pneumonectomy in other series, then there would be good ground for favouring " policy lobectomy "

The ratio of pneumonectomy to lobectomy was found to be 4 1 There was wide variation between the results of pneumonectomy among the various surgeons, but there was close similarity between the lobectomy figures The reason for this discrepancy is not far to seek, the indications for lobectomy vary little, whereas there may be considerable difference of opinion as to what patients are suitable for pneumonectomy and how determined an effort should be made to remove the carcinoma The survival-rates for the conservative surgeons will necessarily be better than those of their more radical colleagues

Fig 8 shows the results of this investigation In all, 859 operations were considered The method of analysis has been different in the three series, but, in order to make the figures as nearly comparable as possible, the operative mortality has been extracted from Sellors's (1955) figures, and the figures of Bignall and Moon (1955) have been reanalysed by almost the same method as was used in the present series (A J Moon, personal communication) The only remaining difference in the analyses is that in the two series with which the present one is compared all the survivors at a given period were included whether or not they died later In the present series only those still alive at the time of analysis were considered It is apparent that there is a close similarity between the three series in the four year and five year periods, when the great majority of the patients who were going to die of their carcinoma had done so, but earlier than this the different method of analysis had caused a considerable discrepancy

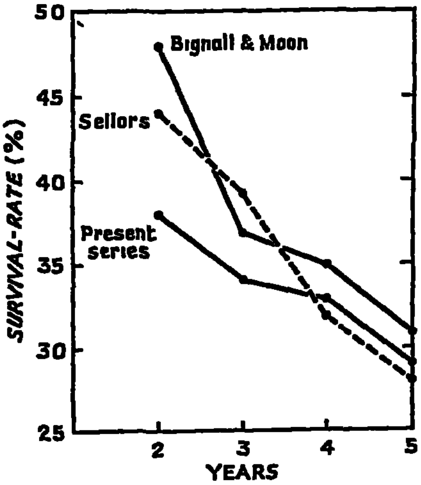

Fig 8—Survival rates after all resections by surgeons contributing to present series, compared with analyses by Bignall and Moon (1955) and Sellors (1955)

The influence of glandular metastases on the prognosis in bronchial carcinoma cannot be overstressed The question arises Can a radical lobectomy be performed? Several reports have described the lymphatic drainage of the lung, and Borrie (1952) traced the lymphatic pathways of individual lobes as far as the bronchopulmonary glands, but until these pathways have been traced still further to the mediastinal glands the planning of a radical lobectomy will not be feasible Recently Nohl (personal communication) has found that the drainage of individual lobes is consistent Extension of this work may show that it is as irrational to recommend pneumonectomy for an upper lobe tumour as it would be to remove the entire colon for carcinoma of the sigmoid

Boyd et al (1954) have already described a form of " radical lobectomy," but the operation cannot become established until lymphatic spread has been further investigated and until more information is available about the submucous spread in the bronchus proximal to the carcinoma

The present series appears to justify continuation of the policy of " lobectomy where possible " in the treatment of bronchial carcinoma It is hoped that when more is known about local spread of the disease the present figure of 10% of deaths from local metastases may be reduced

Summary

The results of 264 lobectomies for bronchial carcinoma were investigated

The two year survival rate was 50% and the five year survival-rate 61%

Patients with adenocarcinoma had the best prognosis and there was no difference between the prognosis for patients with undifferentiated and with squamous cell carcinoma

The presence or absence of glandular involvement had a close bearing on prognosis

Uncircumscribed tumours were associated with a slightly better prognosis than circumscribed tumours

Patients who underwent lobectomy for palliation did not do as well as those in whom the operation was carried out as a policy

The site of the tumour was unrelated to prognosis

Of the 119 deaths, 47% were due to general metastases, 23% to local metastases, 10% to the operation, and 16% to causes other than carcinoma

90% of the patients who died of metastases did so within two years of operation

There is probably a place for " lobectomy where possible " in the treatment of bronchial carcinoma

Since unrestricted visits is the first essential for the patient a mental hospital, let *all* our mental hospitals throw open ide their doors—and keep them open —H G WOODLEY 'dzell, Angus)

accinia versus Poliomyelitis —Relative to Dr MacIver's cond communication (March 17), I would say that in urban eas in the United States smallpox vaccination takes place lmost universally before the child is a year old In some ral areas this vaccination will not be given until the child nters school, but I would not hazard a guess at the percentges concerned Many children are re vaccinated on going o school, and in the Service almost 100% of children as well s parents are vaccinated every three years Unfortunately oliomyelitis still occurs among our personnel It is to be hoped hat Dr MacIver's observation is correct, for it would be just ne more good argument for vaccination against smallpox— disease we can control —Colonel CHARLES H MORHOUSE, D (Third Air Force, Ruislip, Middlesex)

Production of Codeine —Dr Williams (March 17) shows a lamentable lack of knowledge of the pharmacology of acetanilide and related compounds, and appears to be unaware of the excellent work that has been done in this field by Brodie and others (B B Brodie, J Axelrod, *J Pharmacol* 1948, 94, 22, 29, F B Flinn, B B Brodie, *Ibid*, p 76 B B Brodie, J Axelrod, *Ibid*, 1949, 97, 58) Acetanilide is a dangerous drug because the body de acetylates part of it into aniline It is not generally considered, however, that it causes agranulocytosis Similarly, phenacetin is partially de acetylated into another, though less dangerous, amine, *p* phenetidine The active non toxic metabolite of acetanilide and of phenacetin is *n* acetyl-*p* aminophenol, which is 'Panadol'

To convert *n* acetyl *p* aminophenol into acetanilide the body would have to de hydroxylate it—a process that is unknown for phenols which are metabolised in the reverse direction by further oxidation, conjugated with glucuronic and sulphuric acids, or excreted unchanged

More than two million doses of *n* acetyl *p* aminophenol have already been given to humans, and there have been no authenticated reports of toxic effects All the available evidence suggests that panadol is a safe analgesic and one that is unusually free from side effects, which is the main reason for using it —L M SPALTON, B PHARM, director, Bayer Products Ltd (Kingston on Thames)

Medicine and the Law

Death due to Penicillin

AN anaphylactic reaction to penicillin caused the death, on Feb 3, of a man of 34 who the day before had undergone *tonsillectomy* at the Radcliffe Infirmary, Oxford[1] At the inquest the patient's doctor said that last October he had attributed symptoms in this man to hypersensitivity to penicillin. A dermatologist had concluded that a rash which had developed was due to a throat infection After the operation penicillin was ordered (nothing then being known of the hypersensitivity) A rash developed, and the treatment was changed A staff nurse noted this in the change book but did not remove the patient's name from the penicillin list On Feb 3 another nurse, about to inject penicillin, was told by the patient that he was hypersensitive She relied on the list

Obituary

Sir MORTON SMART

Sir Morton Smart, G C V O, D S O, manipulative surgeon to King George VI and consultant in physical medicine to the Royal Air Force, died on March 16 at the age of 78 He was born in Scotland, the third son of John Smart, R S A, and graduated M.B from the University of Edinburgh in 1902 During the South African war, he had seen active service and in the 1914 18 war he again served as a combatant, this time as a *commander in the* R N V R, *and* was in charge *of a gun*boat flotilla at the Dardanelles This background of Service experience sharpened his interest in the problems of reablement He was' especially concerned with the application of his specialty to the problems of the casualties of war and industry and in 1940 he addressed a committee of the House of Commons on Physical Medicine in War time

Dr WILLOUGHBY-LYLE

We hear with regret of the death on March 13 of Dr Herbert Willoughby-Lyle An indomitable little man, full of energy and activity, he lived to the age of 85 And he lived to the full He was a famous physiology coach in his youth, a first class ophthalmologist in his prime, a vivid medical teacher, and for over 20 years dean of King's (whose medical school he completed by his own exertions) His association with the school began as a student and ended as dean emeritus it stretched from 1887 to 1931 and amply qualified him to turn historian His book, *King's and Some King's Men*, appeared in 1935 and he published an addendum five years ago He was a highly individual and lovable character, who will not be forgotten by his school or by the thousands he served Two of his family, Mr T Keith Lyle and Dr Eric Lyle, are members of the medical profession

News

The trials with an oral attenuated live virus poliomyelitis vaccine, now being carried out in Northern Ireland under the direction of Prof. G W A. Dick, are being extended to include medical students and children whose parents have agreed to their receiving the vaccine Only those volunteers with no antibody to one or other types of virus will be given the vaccine

On Feb 25 the degree of M D of the University of Cambridge was conferred on Robert Marshall, D.N Phear and Arnold Pines the degree of M B on J A Eddington and J F M Newman, and the degrees of M B B CHIR on J F Garner

The Royal Society of Tropical Medicine and Hygiene has awarded the Manson medal for 1956 to Brigadier J A Sinton, V C F R S

CORRIGENDA *Prevention of Hay fever* — Piriton maleate mentioned in Dr Stathers letter (March 10) is *chlorpheniramine* maleate

Chest Radiography in Pneumoconiosis —In our leading article last week the last sentence in the second paragraph should have begun, "When allowance is *made for* Durham miners going to the coalface ten years *later* than their Welsh colleagues '

Alkaline phosphatase (units per 100 ml)	12·4 (3–66) 11·5 (3–45) *(25)*	15·2 (3–66) 13·2 (3–33) *(14)*	11·6 (3–14) 11·4 (7–27) *(6)*

Values given are means ± S.D. or range, upper values preoperative, lower values postoperative. Number of cases in italic numerals in parentheses.

P values for difference between mean results at *x* years and before operation calculated by "Student's" *t* test.

cirrhotic liver was not followed by any greater immediate deterioration in hepatic function than that after other operations of comparable severity in patients with cirrhosis and (2) there was no significant difference between the results of hepatic function tests before and at 1–2 years after operation in patients who survived. The follow-up of these patients has now been extended and the findings essentially confirm our previous report.

The results of hepatic function tests immediately before operation have been compared with those at intervals of approximately 12 (11–17), 36 (33–40), and 60 (50–70) months after operation (table II). The tests and the analytical methods have already been described (Macpherson et al. 1954). For each test the mean postoperative values are compared with the corresponding mean preoperative values. When the scatter in the values is small it has been expressed as a standard deviation, when large, as in the values for alkaline phosphatase and serum-bilirubin, as a range.

The analysis (table II) shows that there is a significant difference between the results of the tests of hepatic function before and at the stated intervals after operation in 2 instances only (the plasma albumin and total protein levels at 1 year). The changes in all other tests were not significant, where they have been calculated, or obviously insignificant when only ranges are given. Thus operations for portal hypertension have not had permanent or progressive adverse effects on hepatic function in patients who survive them for up to 5 years.

In table III results are analysed according to whether the operation was splenectomy alone or a portal-systemic anastomosis. Apart from the rise in the plasma-albumin level at 3 years after splenectomy alone, none of the changes is significant. It may be noted that in the patients submitted to splenectomy alone the mean preoperative values for albumin and total protein were lower than in those submitted to portal-systemic anastomosis. However, the difference was significant only for albumin (P<0·01 and P<0·1 respectively). The corresponding values for globulin were higher, but not significantly so (P<0·7). Other values did not differ appreciably. These differences are probably attributable to the fact that the less severe operation was deliberately performed in some patients who were considered very poor surgical risks. After operation the difference between the two groups became smaller. It may be concluded that deviation of portal blood from the cirrhotic liver, whether partly by splenorenal (8 cases) or entirely by portacaval (1 case) anastomosis, did not cause any significant deterioration of hepatic function over a period of 3 years after operation.

One further analysis of the results was carried out. Other workers who have reported the progress under medical treatment of patients with cirrhosis (Post and Patek 1942, Ricketts et al. 1950, Douglass and Snell 1950) have observed a correlation between the level of the plasma albumin when the patient was first seen and the prognosis. In the present series no significant correlation was found between the survival time after operation and the preoperative values for albumin, globulin, and total protein (r = +0·20, +0·08, and −0·26 respectively).

Peripheral-blood Picture

The short-term effects of operation on the peripheral blood picture in 58 cases of portal hypertension have already been described (Macpherson and Innes 1953

TABLE III—HEPATIC FUNCTION BEFORE AND AFTER OPERATION IN PORTAL HYPERTENSION: ANALYSIS BY OPERATION

Quality of Marriage

THE Royal Commission on Marriage and Divorce were asked to have in mind "the need to promote healthy and happy married life and to safeguard the interests and well-being of children" The most constructive and original of their recommendations[1] suggest new ways of protecting children and of preventing and repairing broken marriages

They are concerned at the sharp increase in the number of divorces during the last 20 years—27,471 in England and Wales in 1954 compared with 4735 in 1937—but they do not believe that marriage will be saved by making divorce more difficult Indeed they are evenly divided on whether the final breakdown of a marriage should not be recognised as grounds for divorce Of the nineteen members, nine recommend that when a husband and wife have lived apart for 7 years either spouse should be able to obtain a dissolution of the marriage provided the other spouse does not object Four of these members are prepared to waive the second spouse's consent if the separation can be shown to be due to his (or her) unreasonable conduct This method would make it unnecessary for people to commit a matrimonial offence in order to get a divorce, and would obviate the (often untrue) assumption that one spouse is more to blame than the other

Turning to a problem raised by an advance in medical technique, the commission hold that a wife who accepts artificial insemination by a donor without the consent of her husband is doing him a grave injury which should be recognised as a ground for divorce On the other hand they propose that a husband and wife who agree to artificial insemination, with the semen either of the husband or of a donor, should no longer be able to seek a decree of nullity Another new ground for divorce which has their unanimous support is detention in an institution for 5 years of a spouse who is a mental defective with dangerous or violent propensities They also recommend that, irrespective of the voluntary or other status of the patient, care and treatment in any institution recognised for the treatment of mental illness shall be acceptable as grounds for divorce, and that continuity of treatment shall be held to be maintained so long as the patient's name is retained in the hospital's current records If the patient discharges himself or is discharged but is readmitted to hospital within 28 days, continuity of treatment will also be held to be preserved Subject to these relaxations, they agree that the length of the period of care and treatment should remain at 5 years

Throughout their report the commission point out that their recommendations should be complemented by improved facilities for education, guidance, and conciliation Stepping frankly outside their terms of reference, they propose the development of a carefully graded system of education to fit young people for "marriage and family life," and they ask the Government to set up a body to review the marriage law and arrangements for premarital education and training Present facilities for marriage conciliation they temperately describe as "limited" Proposals to provide legal advice as well as legal aid have not yet been implemented, though 1s spent on advice might well later save £1 on aid The commission believe that this gap should be made good as soon as possible They are anxious that attempts at conciliation should continue to the last possible moment, and fourteen members think that a trial period of conciliation of up to a month should be allowed in cases of desertion and adultery without destroying the grounds for divorce where the trial fails

Every year some 20,000 children under 16 are affected by the divorce of their parents To ensure that this problem is brought home to the parents the commission suggest that a decree should not be made absolute till the court is satisfied about the arrangements made for the children's future This procedure would make clear that the interests of the children are as important as the divorce This constructive proposal illustrates the commission's conviction that, though divorce ends individual marriages, it can yet be one of the buttresses of marriage

Prophylactic Isoniazid

THE successful use of isoniazid in established tuberculosis and the low toxicity of the drug, have prompted the suggestion that it be used prophylactically If isoniazid given at the time of the initial infection prevents the development of tuberculosis, then the drug might be administered to uninfected persons exposed for short periods to a considerable risk of infection To be successful, however, a prophylactic should not only have a low toxicity but it should also either kill all the infecting bacilli or allow the development of a degree of immunity at least as great as that produced by B C G vaccination and it is as yet doubtful whether isoniazid does either of these things

FEREBEE and PALMER[1] have recently reported an experiment designed to test the preventive action of isoniazid in experimental tuberculosis About 1200 guineapigs were given isoniazid, and then infected intraperitoneally with about 5 million virulent tubercle bacilli Treatment with isoniazid was then continued for ten weeks The mortality among the group given 5 mg or more of isoniazid per kg body-weight was the same as in the uninfected control group The treatment of some animals was then stopped for four weeks, after which they were challenged for the second time with the same number and strain of tubercle bacilli To this second infection they showed a degree of immunity similar to that achieved by B C G vaccination of normal animals FEREBEE and PALMER did not investigate or discuss the mechanism responsible for immunity

3. The survival rate after portal systemic venous anastomosis is not significantly better than that in the control series. In its present state the series treated by portal systemic anastomosis is unfavourably weighted by two factors: (1) the use in 12 of the first 14 cases of the Blakemore Lord tube, which has been found to be so commonly followed by constriction or obliteration of the anastomosis that it has been discarded; and (2) a high postoperative mortality during the first 3-4 years of the period under review, when patients who would not now be considered justifiable risks (for example, because of fluid retention and gross ascites) were submitted to operation. Over the whole period there have been 12 deaths in the immediate post-operation period—a mortality-rate of 18%—but in the 4 years ended December, 1955, 36 operations were performed with only 3 deaths (8%). These considerations give us some reason to expect that a report on a larger number of cases in a few years' time will show an improvement on the present figures.

Cause of Death

20 patients died during the period of observation. The principal causes of death (table VII) were hepatic failure, hæmorrhage, and the effect of complications of operation. Usually there was more than one cause, hæmorrhage or operation precipitating the onset of hepatic failure in a patient with a severely damaged liver. 2 patients suffered from tuberculosis after operation and both recovered—a man aged 47 years from pulmonary tuberculosis 1 year after operation, and a girl aged 13 years from miliary tuberculosis 4 years after operation.

P* = Probability of difference in numbers surviving in each exposure period being due to chance alone: calculated from χ^2 distribution (Fisher 1950).

P† = Probability of difference in numbers surviving in whole series being due to chance alone.

TABLE VII—CAUSES OF DEATH (20 CASES)

Causes	No. of cases
Hepatic failure:	
Primary, due to progress of disease	4
Following operation	8
Precipitated by hæmorrhage from varices	13
Complications of operation:	
Mesenteric thrombosis	2
Leakage at œsophagogastric anastomosis	1
Hæmorrhage at the site of operation	1

Intercurrent infection, except as a complication of operation, was not the cause of death in any instance.

Conclusions

The limitations of our analysis must be acknowledged. The number of cases is not large, and in the majority the period of observation has been relatively short. The heterogeneity of the group we believe to be balanced by the series which we have accepted as a control; and so far as we can ascertain, the only important variable in treatment has been the application of major definitive surgery in the cases we have reported. Finally, the statistical method is necessarily concerned with an impersonal analysis of the whole problem of portal hypertension as it has been presented. The individual patient seldom conforms to the mean of a series. Nevertheless, statistical analysis of the results of treatment in a changing pathological condition can provide guidance in particular cases, because it takes account of the failures as well as the successes, of the lapse of time since the treatment was undertaken, and of the natural history of the disease.

The following tentative conclusions have been drawn from our data:

1. Gastro-œsophageal bleeding is more likely after operation for portal hypertension associated with hepatic disease when it has been a presenting feature of the condition. Splenectomy alone is not the elective operation when there has been hæmatemesis or if œsophageal varices can be demonstrated, but is a satisfactory procedure when splenomegaly and hypersplenism are the presenting features. A portal systemic anastomosis which remains patent does appear to provide some additional protection against recurrence of bleeding; but further evidence from a larger series and a longer period of observation is required, because the onset of bleeding may be long delayed after such an anastomosis has been occluded by thrombosis. Limited œsophagogastrectomy appears to be a satisfactory method of treating recurrent bleeding after other operations.

2. Hepatic function was maintained in patients who survived 5 or more years after operations which sometimes involved deviation of all portal blood from the liver by portacaval anastomosis. In most instances, these were patients whose hepatic function was not greatly impaired before operation. When there is ascites or other evidence of severe hepatic dysfunction, operation should be postponed. If the indications for operation are urgent, the smallest procedure appropriate to the circumstances should be performed.

3. The leucopenia and thrombocytopenia which are characteristic of portal hypertension can be corrected immediately by splenectomy, and follow-up for 5 or more years shows that the improvement is maintained. Sometimes the power of resistance to infection has been noticeably increased after splenectomy. The anæmia usually responds rapidly to large doses of iron and to reduction in the frequency and severity of alimentary bleeding.

4. Statistical comparison of a series of patients treated medically with a series treated by operation in addition shows that the survival rate is slightly, but for the most part not significantly, better in the patients submitted

namely, that the pathogenesis of both clinical signs and changes depends largely on the nature and extent of the tigen antibody clash within the theca

TRIBUTE TO SIR THOMAS FAIRBANK

In a special issue of the *Journal of Bone and Joint Surgery,*[1] tive both in contents and in size, British orthopædic rgeons offer their affectionate tribute to Sir Thomas Fairbank his eightieth birthday For more than half a century he s enriched their branch of surgery, not only through his aching and publications, but also by his human qualities of ndness, understanding, and readiness to help selflessly and thout ostentation

This volume is a worthy tribute The subjects range from a storical review of British orthopædic surgery, a field in which homas Fairbank has already taken a permanent place, to rare seases of the skeleton, a subject in which he is today the orld's greatest authority St J D Buxton and Julian ylor have undertaken what must have been a labour of love, biographical appreciation of Thomas Fairbank the man, the rgeon, and the soldier, and Sir Reginald Watson Jones troduces the volume with the quotation "I will never be an d man, to me old age is always fifteen years older than am"

Sir **Russell Brain** has been re elected president of the oyal College of Physicians of London for the coming year

OCIAL REHABILITATION UNIT, BELMONT HOSPITAL, SUTTON

There is general agreement about the need to keep ven chronic regressed patients occupied where possible, ut, like so many other aspects of mental-hospital life, he different approaches to occupation have, as yet, een little studied We are still applying methods largely ccording to personal conviction, without a thorough nderstanding of what we are doing

The occupation offered to patients is, broadly speaking, f two kinds they may spend some part of their time n handicrafts in the occupational-therapy department, or hey may spend more regular hours on productive work f a patient is too ill to perform any but very simple asks, occupational therapy as given in most mental ospitals may help If his interest can be obtained in ome simple or familiar work, and particularly if the ccupational therapist can enter into a supportive relaionship with him, even the most elementary occupation nay be therapeutic it may bring out and direct controctively a variety of emotions which have been denied utlet, and it may do something to offset the restrictions f the mental hospital régime As now usually practised, owever, occupational therapy cannot claim the rehabiliative effect of productive group work, which is capable f leading to better contact with reality, to behaviour nore in accordance with social standards, and to the oundations of self esteem

In a simple form productive work has long been offered in most, if not all, mental hospitals, where patients help in the kitchen, laundry, or farm In some more progressive hospitals these essential services have been reorganised to offer patients a wider range of occupations From this in turn have developed experiments in the creation of workshops within the hospital, where patients are employed under near-factory conditions Because this more positive use of group work as a form of therapy is still largely empirical, our experience at the Social Rehabilitation Unit at Belmont Hospital may be worth describing in the present series of articles

A SLOW START

For some years we had great difficulty in persuading our patients with character disorders and poor employment records to show any interest or enthusiasm in the workshops They resisted the idea of work no matter how necessary this might seem to the staff Even when we pointed out that the work was valuable for the whole unit, we did not arouse enough interest and support to make the workshops function well Moreover the patients resented the absence of any money incentive

We had started off with the rather vague idea that the workshops should have some relation to future work and training for a job With this end in view we sought advice from the Ministry of Labour, who were most helpful At that time, soon after the late war, the building trades were short of trainees and we were advised to establish three working groups under the supervision of a trained bricklayer plasterer, and carpenter To this we added the occupations of hairdressing, gardening, and tailoring We avoided handicrafts for the men and chose something more related to ordinary work But, though a certain amount of useful building was done and the other workshops had their willing workers, the patients as a whole continued to grumble about the work programme, and we ourselves were diverting a great deal of energy into developing other community methods of treatment At that time we tended to think of the occupations as a preparation for training in those particular trades In retrospect, however, it seems clear that we never really expected that they would be of much use in helping the patient to choose a trade or as early training for it

During the last three or four years conditions have changed despite these difficulties We have become increasingly aware that patients will not take an active part in work therapy unless they are interested and identify themselves with the workshops We came to realise that the work would become meaningful to the patients only when the tasks met some of their fundamental needs

Because we were housed in a neglected bomb-damaged building, there was a real need to redecorate the rooms to make our home more cheerful The rooms contained many broken-down pieces of furniture which urgently needed attention if we were to have any pride in our surroundings, let alone any comfort Again, many of the patients were destitute and received only *7s 6d* a week pocket-money from the National Assistance Board so they needed new clothes or at least repair of those they had Also, their monotonous diet could be varied by growing more vegetables By forming a home group, we shifted the emphasis from prevocational training to work to meet the more urgent needs of the community Now we have five groups—furniture repair, painting and decorating, gardening, tailoring, and home groups—all engaged on tasks relevant to the needs of the community, and the patients' attitude to work has changed In observing the social processes within the groups we have been helped by weekly workshop discussions, which were suggested by the patients themselves These are attended by the patients, the social therapists who work with them alterations of urinary excretion of electrolytes during the first three days' treatment Of these 10 patients 3 gave no significant renal response to acetazolamide and showed neither a diuresis nor a loss of weight In the remaining 7 patients the cumulative increments of urine flow were 1 1–6 4 litres The increase in daily volume of urine appeared to be closely related to the increase in urinary excretion of sodium which was 64–624 m eq by the third day

---

* A group of articles chiefly concerned with the value of active occupation and work for mental patients and the means whereby it is best provided

The increase in urinary excretion of sodium and potassium was in most cases about the same as the increase in excretion of bicarbonate, which averaged 119 m eq after twenty-four hours and 159 m eq after seventy-two hours Only cases 9 and 10 showed a satisfactory diuresis and clinical response to acetazolamide, and in both these patients the increase in urinary excretion of sodium was accompanied by approximately equal increments in the urinary excretion of both bicarbonate and chloride

Comparison of Effects of Mersalyl and Acetazolamide

Fig 2 shows details of the daily volume of urine and urinary excretion of electrolytes in 15 patients with congestive heart failure, each of whom had three to ten days' treatment with acetazolamide and with mersalyl alternately Acetazolamide 0 25–1 00 g was given either daily or on alternate days and mersalyl 2 ml on alternate days in most cases, but in some on successive days, each injection being preceded by an oral dose of ammonium chloride 2–4 g A representative example of the dosage schemes used is shown in fig 3 The data in fig 2 are the averages of all the days on which each drug was administered and thus represent the net effect of the diminishing response to acetazolamide, as already described

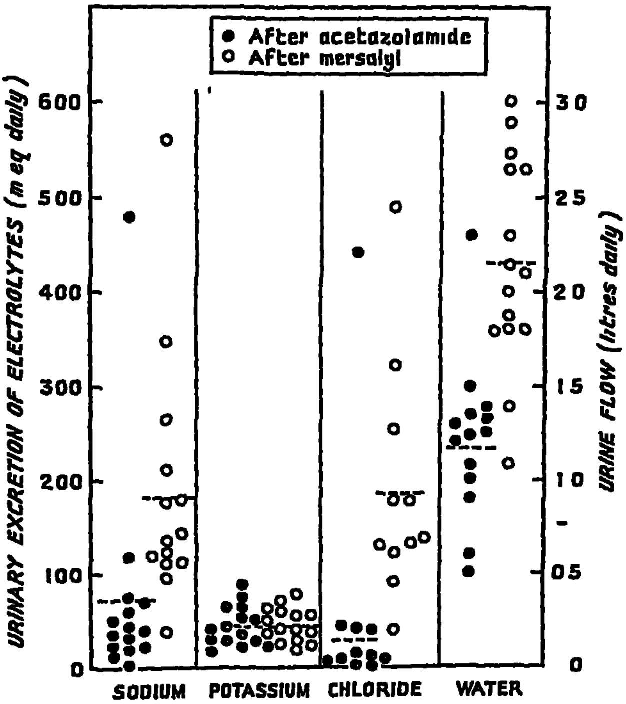

Fig 2—Average daily urinary excretion of water and electrolytes by 15 patients treated with acetazolamide and mersalyl horizontal lines represent mean values for all patients

In the group as a whole the diuresis effected by mersalyl was considerably greater than that caused by acetazolamide the average daily volume of urine of the 15 patients was 1 2 litres during treatment with acetazolamide and 2 2 litres during treatment with mersalyl The average daily urinary excretion of sodium was 182 m eq under treatment with mersalyl but only 73 m eq under treatment with acetazolamide The average daily urinary excretion of potassium caused by each diuretic was 44 m eq (fig 2) The dependence of the diuretic effect of both drugs on increased urinary excretion of sodium is illustrated by the results in 2 patients with hypertensive heart failure (fig 4) whose daily intake of fluid was strictly limited to 1 5 litres each

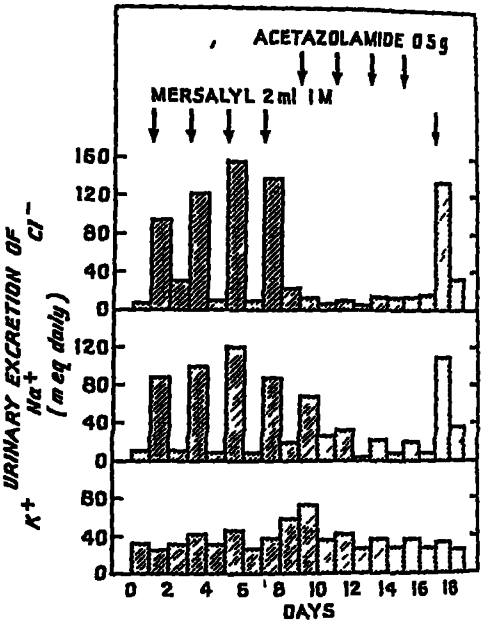

Fig 3—Comparison of effects of acetazolamide and mersalyl on urinary excretion of electrolytes in a representative patient.

Judged by loss of weight and by the decrease of oedema and venous pressure, the therapeutic effect of acetazolamide was inferior to that of mersalyl in 12 of the 15 patients 5 patients gave no response whatever to acetazolamide, 1 of these was also almost wholly resistant to mercurial diuretics 2 patients who had a large diuresis and a good therapeutic effect from acetazolamide also had an exceptionally good result from mersalyl

Fig 3 illustrates a representative example of the changes in electrolyte excretion brought about by

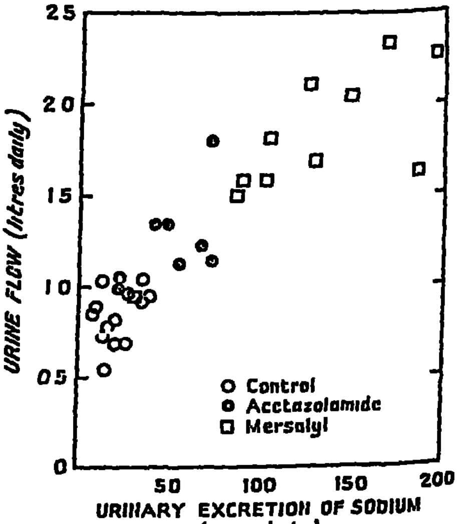

Fig 4—Urine flow and urinary excretion of sodium in 2 hypertensive patients with heart failure during control period (no treatment) and under treatment with acetazolamide and mersalyl

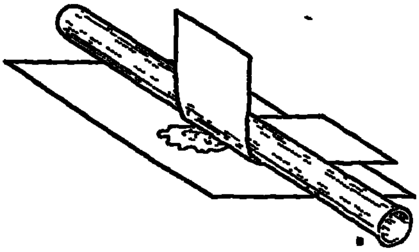
LLULOSE ACETATE FILMS AS A SUBSTITUTE FOR GLASS SLIDES IN HISTOLOGY

P N KARNAUCHOW
M D
om the Department of Pathology, University of Ottawa, Canada

ALTHOUGH plastic materials are commonly employed
r mounting large pathological specimens, they do not
em to have been adopted in histopathology The
ea of using cellulose acetate film as a substitute for
ass slides was borrowed from photography and radio-
gy, where the cost and bulk of glass plates caused their
andonment a long time ago The lightness and
mpactness of plastic are properties which commended
as a mount for microscopic sections, especially where
ts of slides were to be used for teaching Furthermore,
astic slides could be mailed in ordinary paper envelopes



g 1—Covering section mounted on a film slide with a strip of Scotch tape, using a test-tube as a roller

ccordingly an attempt was made to discover whether
ides made from strips of cellulose acetate are accept-
ble for histopathological preparations—strips of Scotch
ape being used instead of cover slips

rocedure

The photosensitive emulsion is removed from ordinary
-ray films by soaking them in hot water The film is
hen cut into strips 5 cm wide and placed in a 50%
olution of concentrated hydrochloric acid for two to
ve hours to remove the residue of the gelatin base
fter this the strips are washed well in tap water, dried,
nd cut into 6 5 cm lengths

The tissue sections are floated in a waterbath in the
sual way and picked up on the film slides Adhesives
gg albumen or gelatin solutions) are not necessary,
ecause capillary tension is sufficient to hold the section
the slide The film slides are allowed to dry and
laced in the spool of a universal ' Kodak ' film develop-
ng tank, where they undergo deparaffinisation, washing,
taining, dehydration, and clearing in the normal way
or deparaffinisation and clearing a variety of agents,
ncluding toluol, xylol, and benzene, give equally good
esults After staining and clearing, a piece of Scotch
ape (transparent adhesive plastic) 3/4 in wide is
mmersed in a clearing agent until the adhesive material
ecomes swollen and rolled over the film slide bearing
he mounted tissue section this is done with a test
tube, exerting even pressure (fig 1) The covered film slide is allowed to dry for a short while, wiped with a cloth, dipped into the clearing agent to remove the excess adhesive, and then trimmed

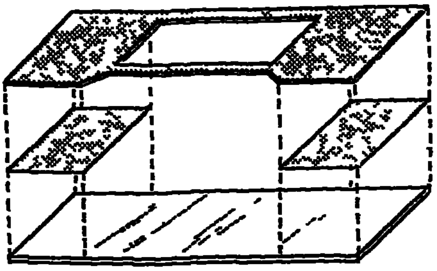


Fig 2— Exploded view of the viewing frame

Because the film slides are neither flat nor rigid, a frame was made to hold them while they were being examined under the microscope An "exploded" view of the frame is shown in fig 2

Two small rectangular pieces of uncleaned X ray film were glued to opposite ends of a glass slide leaving a space between them 5 cm long (the width of the film slide) Over this was glued a piece of strong, thin cardboard the same size as the glass slide, with a window 22 mm × 40 mm cut out of its centre When viewing, the film slide is pushed into the slot between the cardboard and the glass slide

Results

Under the microscope, tissue sections prepared in this way had the same appearance as sections on glass slides Scotch-tape covers were also found to be satisfactory when used with glass slides, and no difficulty arose when sections thus covered were examined with the oil-immersion objective The cellulose-acetate films were not affected by any of the reagents and stains in common use The material had sometimes been scratched during the removal of the emulsion, but the scratches were not usually seen when the sections were in sharp focus

Slides prepared in this fashion and kept in an ordinary slide box at room-temperature for four years have shown very little change The very slight clouding of the Scotch-tape adhesive does not interfere appreciably with examination of the sections The tissue shows no drying nor is there fading of the stain ; the Scotch-tape covers remained flat on both glass and film slides The microphotograph in fig 3 was taken when the preparation was two years old, and it has shown no change since then

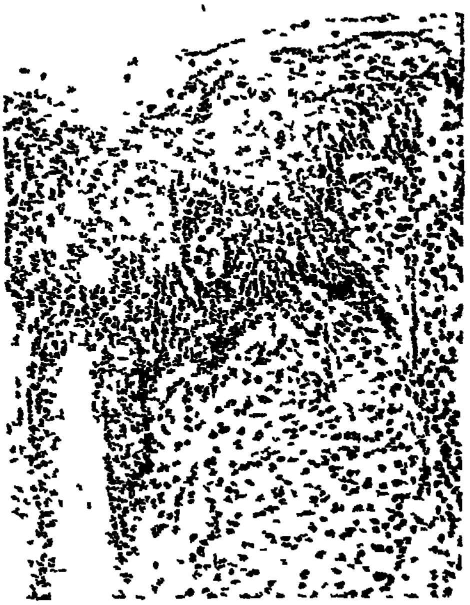

Fig 3—Chronic cervicitis Cellulose acetate film with Scotch tape cover (Hematoxylin and eosin × 485)

The main disadvantages of the use of these materials are the tendency of the film slides to curl slightly which, however, can be overcome by using the simple viewing frame described) and the slight clouding of the Scotch-tape adhesive Perhaps, if there were a need for it, an adhesive could be devised which would remain clear

The advantages include cheapness, ease of storage, and particularly convenience of transport, since they are light and unlike glass, need no protective packing

HÆMATEMESIS

CONTROLLED BY ADRENALINE AND STYPVEN

W J M Brandon
OBE, MB Edin, FRCSE
CONSULTANT SURGEON, LAW HOSPITAL, CARLUKE, LANARKSHIRE

"The effort to distinguish those patients who would recover without timely operation from those who would die without it has not been unsuccessful and still proceeds" (Aird 1949)

Any discussion on the treatment of gastroduodenal hæmorrhage still tends to resolve itself into arguments for and against surgical intervention Meulengracht (1935) was primarily responsible for the slow acceptance of surgical treatment, and he accomplished it with a single sentence "I consider a mortality of 1 or 2 per cent on dietary medical management makes the question (of operation) unreal to me and relieves me of the responsibility of having to decide in an individual case whether operation is advisable or not" (Aird 1949) It is very tempting to follow such a guiding principle, which says in effect "do nothing apart from performing a few simple rites, never make a decision, and salve your conscience with the knowledge that you will have achieved the best possible results" With this stroke, Meulengracht left his rivals, Gordon-Taylor and Finsterer, crying like voices in the wilderness What chance had a gospel of decision and selective action against an appeal such as this!

As so often happens, the truth lies somewhere between the diametrically opposed views, and it is now recognised that there is "an irreducible minimum of 10 per cent of sufferers from serious hæmorrhage who are condemned to death by the refusal of operation or by delay in advising it" (Aird 1949)

The crux of the problem is how to identify at an early stage the patient with "surgical" hæmatemesis, who is "bleeding from an artery of anatomical size fixed in scar tissue at the base of a chronic ulcer" (Ogilvie 1955) This cannot always be done with certainty, but the selection of patients for operation has been simplified by a slight bending of the facts to provide a clear-cut criterion for surgery, based on a logical conception of the underlying pathology Working on an 80% probability, the indications for operation are repeated or continued bleeding during medical treatment, middle age, a history of previous hæmorrhage, and pain preceding hæmorrhage Of these indications the first is naturally the most important, but, unfortunately, equally copious and repeated bleeding can result in the early stages from an acute lesion, and an acute lesion can be the real source of bleeding, though a chronic lesion is present as well

It is a pity to ablate the greater portion of an otherwise healthy stomach because of an acute transient lesion, or to operate on a quiescent chronic lesion at a time when the patient is least suited to undergo operation It is even more humiliating when the lesion comes to lie on the wrong side of the gastric resection and is demonstrated subsequently at necropsy These unhappy possibilities are covered by a bald though inaccurate statement that the bleeding from an acute lesion is never severe enough to be alarming If emergency surgery is undertaken in every case of serious and repeated bleeding, it means that a larger proportion of cases will be exposed to a risk by no means negligible in patients of this age and in this condition Surgery would be better confined to those patients who can be saved only by operation

TABLE I—NO OF PATIENTS ADMITTED AND MORTALITY RATE

Year	No of patients admitted	No of deaths and mortality rate
1950	68	8 (*12 1%*)
1951	79	10 (*12 6%*)
1952	79	9 (*11 4%*)
1953	93	9 (*9 7%*)
1954	92	6 (*7 6%*)

This leaves the discussion evenly balanced, the physician may lose a patient who could have been saved by surgery, and the surgeon may lose one by early operation who would have recovered spontaneously

Review of Past Experience

This review covers a period of five years (1950-54) during which time all cases of hæmatemesis were regarded as medical problems, and only those patients needing surgical treatment were referred to us by the physician

Table I shows the number of patients admitted to the Law Hospital with frank hæmatemesis and it also shows the total mortality-rate Like Tanner (1950), I feel that the total mortality-rate is a true index of therapeutic success, which depends on the closest liaison between physician and surgeon

Table II includes only those patients who had simple gastroduodenal lesions which failed to respond to medical treatment The figures quoted are *statistically* insufficient, but they provide a basis for discussion

TABLE II—PATIENTS TRANSFERRED TO SURGICAL WARD AND THE RESULTS OF OPERATION

Year	No of patients transferred to surgical wards	No of patients with chronic ulcers	No of patients with acute lesions	No of emergency operations	No of delayed elective operations	No of postoperative deaths	No of non-operative deaths	Total no of deaths
1950	3	2	1	3	0	1	0	1
1951	1	1	0	1	0	0	0	0
1952	8	7	1	8	0	4	0	4
1953	16	11	5	2	7	0	2	2
1954	11	7	4	2	5	0	0	0

These tables cover a period from routine medical treatment (1950 and 1951), through a period of this treatment combined with emergency gastrectomy (1952) to the present method, started in 1953 and finally established in 1954

Table I shows that there was no significant change in the over-all mortality-rate until 1954, and table II shows that nearly the same number of patients died in 1952 as in previous years, but that a higher proportion did so in my surgical wards

By the beginning of 1953 I became convinced that emergency gastrectomy was not the solution in the late stages of hæmorrhage A mortality rate of 50% in these cases compared with under 2% for 276 elective gastrectomies was disquieting No patient presented an insuperable technical difficulty and all had been prepared, and treated postoperatively, on recognised lines In the late stages of hæmorrhage, adequate restoration of blood volume with control of the bleeding by operation was not always successful, and it occurred to me that if I could devise some means of controlling the bleeding till a full physiological stabilisation could be attained, the results of operation would be more favourable In other words, I could choose the time and conditions for attack

Adrenaline and Stypven

The most feasible solution appeared to be a powerful styptic which could be given safely by mouth I had seen Russell's viper venom ('Stypven') used some years previously by my colleague, Dr J Bryant, in perfect safety, but with equivocal results It struck me that the reasons for its uncertain action were its inability to produce an occlusive clot in the presence of active bleeding and the unlikelihood of its entering the duo

Letters to the Editor

Tuberculosis Then and Now —Your annotation (Feb 11) s already been admirably answered by Dr Macdonald eb 25)

Most of your criticism seems to be based on comparison th the present state of other specialties Is it true that there no place for a comprehensive neurological service or a skin rvice or a heart service? Why should these ideas appear congruous except from the standpoint of our grandparents? In this city of 508,000 inhabitants, the notified deaths in 55 from three respiratory diseases were as follows bronchitis 3 pulmonary carcinoma 270, respiratory tuberculosis 67 f the 385 deaths from chronic bronchitis, the majority were the 65–75 age group (132 men and 52 women), and it would ot be unfair to assume that the men had on an average been nable to work for 10 years before they died Surely this is a ocial problem of some magnitude

Since 1948 we have been trying to run a comprehensive ealth service Why quibble at a comprehensive chest service? –A R BUCKLEY, M.R C P (Leeds Chest Clinic)

"Infectious Roseola"—In reply to Dr Keizer (Jan 21), the iagnosis of dengue fever was considered but thought unlikely for he following reasons no initial rash and no secondary rise of emperature on appearance of rash, no bradycardia, joint ains not a feature, rash unlike in appearance and initial istribution, usually no desquamation, no *Aedes ægypti* in he locality —F R FLETCHER, M.R C P (Folkestone)

Inguinal Herniorrhaphy —In this correspondence I have een disappointed to find *no* reference to the work of W J ytle (*Brit J Surg* 1945, 32, 441) May I suggest to Mr Doran that, in case of simple oblique inguinal hernia, after xcising and ligaturing the sac without disturbing the spermatic cord unnecessarily, he gets his anæsthetist to make the patient cough I think he will find that the upper fibres of the arch of the internal oblique muscle do in fact exert a partial shutter action —OWEN WILSON, F R C S E (Bangor)

Sulphonamides and Hypoglycæmia —A few days after reading your leader (Jan 28) I came across the following case

A girl, aged 6 years with mild infection of the upper respiratory tract was given sulphadiazine 0 5 g four times daily Her mother reported afterwards that for two nights running while taking the drug the girl woke up with palpitation, cold sweat, and a feeling of hunger After she had eaten some food the symptoms slowly subsided She had never before had such attacks

The description of the attacks is obviously consistent with hypoglycæmia —E SILBIGER, M D (Beersheba, Israel)

Patent Ductus Arteriosus —With reference to your leading article (March 10) we would like to draw attention to our recent paper on Patent Ductus Arteriosus with Pulmonary Hypertension (*Thorax* 1955, 10, 338) In this we reviewed 9 severely disabled children, aged 1–6 years, with symptoms of this syndrome dating from birth or very early infancy All were subjected to ligation or division of the ductus, and, with 1 exception, in which there was reversal of blood flow through the ductus, all were much improved thereafter 6 of the children were re catheterised at various intervals after thoracotomy and were found to have normal pulmonary arterial pressures and peripheral pulmonary vascular resistances

We concluded that the pulmonary hypertension was secondary to patency of the ductus with increased pulmonary blood flow Therefore, provided reversal of blood flow through the ductus is not present, it would appear that early operative treatment in these cases is essential to prevent irreversible changes in the pulmonary vessels —IAN M ANDERSON, M.R C P, H M T COLES, M.R C.P (Westminster Hospital, London, S W 1)

News

Sir James Paterson Ross and Prof W Melville Arnott have been appointed Sims Commonwealth travelling professors for 1957

Prof Carl Semb of Oslo will give a Moynihan lecture at the Royal College of Surgeons of England on Friday, April 20 at 4 P M on Partial Resection of the Kidney

Dr G S W Organe Dr B R M Johnson and Dr A I P Brown have been elected to the board of the Faculty of Anaesthetists of the Royal College of Surgeons of England

Under the Therapeutic Substances (Control of Sale and Supply) Regulations, 1956, which come into force on March 31, bacitracin, and tetracycline and viomycin and their salts are brought within the scope of the Penicillin Act, 1947, under which they may be supplied only on prescription

The Minister of Health s policy on comprehensive health centres is explained in a letter to London County Council The Minister is averse to the acquisition of sites long before they are needed and future centres should be considerably smaller than that at Woodberry Down Centres says the Minister should secure the closer association of the local health authority services with other services especially the general medical services and generally conditions for a centre will be suitable only in large new housing areas London County Council has agreed in principle to release sites reserved for comprehensive health centres except parts needed for local authority services

On Wednesday April 4, at 5 30 P M, Sir Henry Dale O M F R S will open the Wellcome Museum of Orthopædics at 234, Great Portland Street London W 1 The museum which is part of the Institute of Orthopædics will be open daily to students and other medical visitors The first exhibition on the pathology of bones and joints will be held from April 5 to 27

New fellows of the Royal Society include the following members of the medical profession Dr Hans Grüneberg reader in genetics University of London Dr C S Hallpike, director of the otological research unit of the Medical Research Council, Dr R G Macfarlane Radcliffe lecturer in hæmatology University of Oxford, and Dr W D M Paton professor of pharmacology Royal College of Surgeons of England The list also includes Mr Arthur Wormall D SC professor of chemistry and biochemistry St Bartholomew s Hospital Medical College

The annual general meeting of the Mental After Care Association will be held on Thursday April 19 at 3 P M, at Caxton Hall, Caxton Street S W 1 when Sir Russell Brain P R C P will speak

The British Psycho Analytical Society, to mark the centenary of Freud s birth is holding a series of six lectures on Psycho analysis and Contemporary Thought The lectures will be given at Friends House Euston Road London N W 1 at 8 30 P M on Tuesdays and Fridays beginning on April 13 The lecturers will include Dr D W Winnicott Dr Elliott Jaques, and Dr John Bowlby

in patients who have a slow, persistent oozing from the lesion between attacks of hæmatemesis Nature attempts to combat blood loss by inducing hypotension, which continues so long as there is bleeding Any blood transfusion during this phase produces only a reluctant response from a circulatory system set in hypotension to combat blood-loss, over-loading of the circulation is likely to occur before there is an appreciable rise in blood-pressure The aged, with their less labile vascular tree, are the first to suffer Once oozing has been checked, even the oldest patient responds to transfusion in the normal way

Conclusion

This form of treatment has been in use for the past two and a half years, both in Dr Aitkenhead's wards and my own In no instance has the use of adrenaline and stypven given the slightest cause for anxiety even in the most desperately ill patient

Nearly all the patients transferred to my care have resisted routine medical treatment, but there have been no operative deaths This shows that the method is worthy of a more extended trial than I have been able to make, and it should give equally satisfactory results at the hands of all who wish to use it

In conclusion postoperative bleeding from a gastrojejunal suture line is the one condition least often controlled by adrenaline A bleeding point in the anterior wall of the anastomosis is often recessed between infolded layers of normal mucosa which form an effective barrier to the adrenaline and stypven

I have to thank Sir Heneage Ogilvie for his invaluable criticism and help in the preparation of this paper

PARATYPHOID-C OSTEOMYELITIS OF THE TIBIA

GEORGE WHITE
M B Birm
SENIOR HOUSE OFFICER

M J MEYNELL
M D Sheff, B Sc, M R C P, D P H
CLINICAL PATHOLOGIST

GENERAL HOSPITAL, BIRMINGHAM

OSTEOMYELITIS is a rare complication of salmonella infections Even in typhoid fever, which gives rise to metastatic bone involvement more commonly than any other salmonella infection, the incidence of osteomyelitis has been reckoned to be as low as 0 82% (Winslow 1923) Paratyphoid B is the next in order in frequency, but bone involvement was found to arise in only 2 instances of 1038 cases reviewed by Webb Johnson (1917) Even more rare, judging from the number of reported cases, is osteomyelitis complicating infection with any of the other salmonellæ We have found only 28 reported cases of osteomyelitis due to salmonella other than *Salmonella typhi* or *Salm paratyphi B*, the organisms were *Salm cholera suis* (17) *Salm enteritidis* (5), *Salm typhimurium* (4), *Salm panama* (1), and *Salm oranienburg* (1) We have found no previous report of a case of paratyphoid C osteomyelitis

Case-report

The patient was a Jamaican, aged 40, who had lived in this country for a year and was employed as a metal pickler He had had yaws in childhood He had never, as far as he could remember had any abdominal pain, and careful questioning revealed no past disturbance of bowel habit He was first seen in the casualty department on Oct 25, 1955, when he complained of pain in his left ankle and lower leg which had caused him difficulty in walking and had kept him awake at night for the past six weeks There was no history of a blow or injury to the leg

Examination revealed a diffuse swelling over the lower anterior portion of the left tibia with superficial redness of the skin and severe tenderness to firm pressure over the bone Radiography showed thickening and widening of the distal quarter of the tibia with some central osteolytic areas, well marked periosteal elevation was present, particularly in the lower portions He was admitted to hospital for investigation under the care of Mr J C Fulford His pulse rate and temperature were normal, but, despite bed rest and immobilisation of the leg in plaster, the pain grew steadily worse On Nov 1 radiographic examination of the left tibia showed that the periosteal reaction had increased in extent and thickness Blood count red cells 4,500,000 per c mm, hæmoglobin 90% (13 4 g per 100 ml), white cells 4700 per c mm (polymorphs 70% eosinophils 4 5%, basophils 0 5% lymphocytes 18%, monocytes 7%) Erythrocyte sedimentation rate (Westergren) 42 mm in the first hour, Wassermann reaction negative, serum alkaline phosphatase 8 King Armstrong units

Operation —On Nov 4 the skin was incised and the periosteum was found to be much thickened This was incised and stripped from the bone, to which it was clearly adherent Drilling into the bone resulted in a gush of clear fluid, followed by about 5 ml of yellow pus The marrow cavity was explored, a gauze pack impregnated with yellow soft paraffin was inserted and the skin lightly sutured over the wound

Bacteriological examination —Gram staining of the pus showed no organisms Overnight culture on blood agar yielded a pure growth of gram negative bacilli Subculture on desoxycholate and McConkey's media produced a profuse growth of non lactose fermenting colonies The organism, which was motile, gave the biochemical reactions of a salmonella H and O suspensions of the patient's organism were agglutinated by standard *Salm paratyphi C* sera to a 1 250 dilution The patient's serum agglutinated standard suspensions of *Salm paratyphi C* O to a titre of 1 125 and of *Salm paratyphi C* H to a titre of 1 50 Dr Joan Taylor, of the Salmonella Reference Laboratory, reported "The organism has the following antigenic structure O = 6 7, H = C 1 5 The biochemical reactions confirm the organism to be *Salmonella paratyphi C*" Examination of the urine and fæces on three occasions revealed no pathogenic organism Blood culture on Nov 7 was sterile after incubation for three weeks

Treatment —The organism was found to be fully sensitive to chloramphenicol and accordingly the patient was given 500 mg six-hourly As a precautionary measure he was transferred to Little Bromwich Infectious Diseases Hospital on Nov 9 after removal of the pack from the wound He recovered completely, and the wound is well healed

Discussion

Compared with common pyogenic osteomyelitis (staphylococcal and streptococcal), that due to salmonella infection is usually less destructive and the bony lesions heal more quickly Paratyphoid bacilli are known to linger in the bone-marrow long after they have disappeared from the urine and fæces (Macdonald 1941) Reported cases suggest that as a rule the longer the interval between the acute intestinal infection and the onset of osteomyelitis, the milder is the clinical course of the osteomyelitis itself (Giraccai and Idriss 1952) It is commonly reported that activation of the clinically latent micro organisms can be produced by trauma or physical strain (Lever and Barber 1945), but no such history was obtained in this case Since the osteomyelitis is a late, and sometimes very late, complication of salmonella infection, its nature is unsuspected in most cases, as it was in the present one Only serological studies and, above all, bacteriological examination of pus from the lesion will establish the diagnosis

In the West Indies by far the commonest type of salmonella infection is paratyphoid C In 1952, 584 cases of paratyphoid were notified in Jamaica alone (World Health Organisation 1953) Many immigrants (35,000) have come to Great Britain from the West Indies, and the possibility of paratyphoid C infection should enter into the differential diagnosis of illness in such

LOBECTOMY FOR BRONCHIAL CARCINOMA

J R BELCHER
M S Lond, F R C S
SURGEON, LONDON CHEST HOSPITAL, ASSISTANT THORACIC SURGEON, MIDDLESEX HOSPITAL, LONDON

SINCE 1933, when Graham first successfully resected a bronchial carcinoma (Graham and Singer 1933), the standard operation for this condition has been pneumonectomy Allison (1946), Brock (1948), and Brock and Whytehead (1955) combined pneumonectomy with more extensive dissection of the mediastinum in an effort to achieve truly radical removal of the neoplasm

Pneumonectomy still carries a high mortality Moreover, removal of so much pulmonary tissue necessarily limits the patient's activities, and renders him increasingly liable to become a respiratory cripple On the other hand, lobectomy has been regarded as quite inadequate, and only one paper specifically on this operation has appeared in the English language since 1949 in 1950 Effler described the results in 5 cases

Nevertheless lobectomy has been widely practised, for most reports on the treatment of bronchial carcinoma refer to some patients treated by this operation Sellors (1955) includes 86 cases, there were 74 in the series analysed by Bignall and Moon (1955), Churchill et al (1950) refer to 57, Boyd et al (1954) to 32, and Therkelsen (1952) to 12 All these workers note that the results of the operation are good, but this they attribute to careful selection of the patients they recommend the procedure only for those with small peripheral tumours, for the aged, and for those with a low respiratory reserve

Material

This account of lobectomy for bronchial carcinoma is based on the work of the following surgeons (the number of cases contributed by each is shown in parentheses) K Mullard (35), G Cruikshank (32), C A Jackson (32), M Bates (26), A M Macarthur (20), R Abbey Smith (14), E F Chin (11), M M Brown (11), K Harrison (10), I M Hill (8), B P Moore (8), L Bromley (6), H R S Harley (2), and myself (49) The 1st case was operated on more than six years ago, and the last in May, 1954 In all, 264 patients were subjected to lobectomy All the facts on which this analysis is based were collected by the surgeons concerned

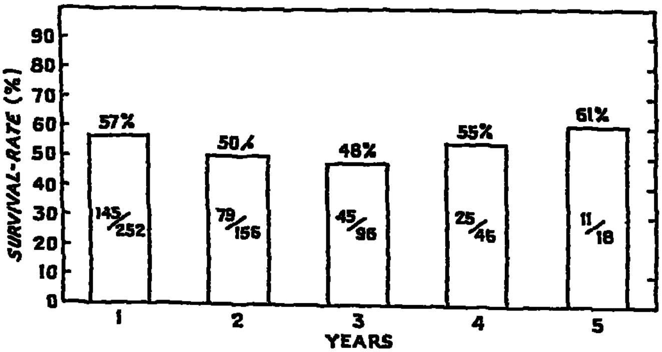

Fig 1—Survival in whole series "Actual" and "possible" survivals are shown inside columns

19 (7%) of the patients were women The distribution of the patients by age groups was as follows

31–40	*41–50*	*51–60*	*61–70*	*71+*
10 (4%)	55 (21%)	117 (43%)	77 (30%)	5 (2%)

Method of Analysis

Survival-rates have been recorded as follows

$$\frac{\text{Actual survival}}{\text{Possible survival}} \times 100$$

The "*possible survival*" consists of the total number of patients operated on in each year, less those who died as a direct result of the operation but including those who died later from causes other than carcinoma of the bronchus

The "*actual survival*" consists of those patients operated on in the twelve month period concerned who were still alive at the time of analysis

The figures have been recorded on a cumulative basis

Results

Fig 1 shows the survival rates for the whole series Of the 264 patients, 12 died at or soon after operation, and of the remaining 252, 145 (57%) have survived for a year or more Of the 156 operated on two or more years ago 79 (50%) survive, of 96 operated on three or more years ago 45 (48%) survive, of 46 operated on four or more years ago, 25 (55%) survive, and of 18 operated on five or more years ago 11 (61%) survive

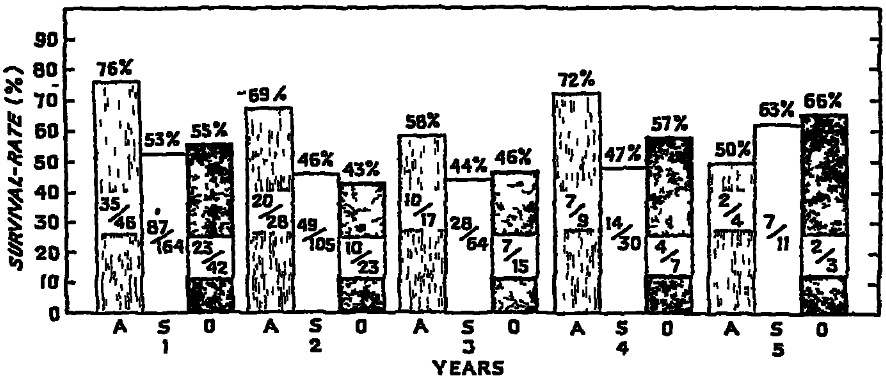

Fig 2—Influence of cell type on survival rate A = adenocarcinoma S = squamous carcinoma. O = undifferentiated carcinoma.

Influence of Cell Type on Results

Although many pathologists were involved in this investigation, there was a wide measure of agreement as to the histological classification of the tumours Three types were recognised adenocarcinoma, squamous carcinoma, and undifferentiated carcinoma Tumours sometimes described as "polygonal cell" and as "transitional cell" carcinomas have been included in the "squamous" group, tumours described as "alveolar cell" and as "columnar cell" have been classified as "adenocarcinomas"

Of the 264 patients 172 (66%) had squamous carcinomas, 49 (18%) adenocarcinomas, and 43 (16%) undifferentiated tumours These proportions are almost identical with those reported by Walter and Pryce (1955) and show how little the cell type of bronchial carcinoma varies with its site

Fig 2 shows the results according to cell type. The patients with adenocarcinoma have the best survival rate (69% at two years), but those with undifferentiated tumours do not appear to have nearly as bad a prognosis when lobectomy has been possible as they do when the lesion is more extensive, their two-year survival-rate is very was obscured by mucus and consisted of greatly exaggerated folds, resembling cerebral convolutions (see figure) These changes were most distinct along the greater curve, where the stomach was up to 4 cm thick, and in this region the muscular coats were also hypertrophied A sharp line of demarcation separated the body of the stomach from the apparently unaffected antrum, and there was no ulceration or scarring of the duodenum

Microscopy—Giant hypertrophic gastritis Infiltration of all coats of stomach, but mainly of mucosa and submucosa, by plasma-cells, lymphocytes, and occasional eosinophils, polymorphs, and macrophages In the more severely affected areas there were occasional micro abscesses, and in these areas, too, fibrosis extended from the submucosa into the muscularis and serosa A small acute ulcer was present in the depths of a fold (a similar ulcer might well have led to hæmorrhage) The inflammation was not confined to the hypertrophied portion of the stomach but extended with diminished intensity towards the pylorus Here and in the adjacent duodenum there were many lymph follicles in the mucosa, some with prominent germinal centres The mucosa was grossly hypertrophic, but it was very well differentiated and there was no suggestion of carcinoma The larger folds seen macroscopically had a connective tissue core derived from the submucosa, while the small secondary folds consisted of mucosa only Mucus secreting cells not only covered the surface and lined the gastric pits, but also extended to the deepest parts of the gastric glands Zymogenic and parietal cells were present in reduced numbers A few glands penetrated the submucosa for a short distance, and some of these, as well as some glands in the deep layers of the mucosa, showed cystic dilatation. Pronounced inflammatory changes (reactive hyperplasia, sinus catarrh, and plasma cell infiltration) affected the greater and lesser curve lymph-nodes

Discussion

In this case the diagnosis was not suspected before or at operation, and it was only after histological examination of the stomach that carcinoma was finally excluded Brunn and Pearl (1926) observed that the diagnosis was usually in doubt until the stomach had been exposed at laparotomy, and, from a study of more recent case reports, this still applies despite improved techniques in radiology and gastroscopy

Maimon et al (1947), describing radiographic appearances, found that the stomach was diffusely involved in each of their six cases, but the greater curve was principally involved The mucosal folds were greatly thickened, indurated, and enlarged, producing an exaggerated saw tooth appearance, often with broad, deep, sharp notches, especially along the greater curve Softness of the rugæ was an almost constant finding, and, as had previously been noted by Spriggs (1943), the flexibility and maintained power of dilatation and contraction of the involved area, and the ability of the peristaltic waves to traverse it, were characteristic findings These observations were, however, largely retrospective In three of Maimon's (1947) cases carcinoma was diagnosed preoperatively, and in only one were the barium meal findings correctly ascribed to diffuse gastric polyposis

Gastroscopic examination, in Maimon's experience, was equally unrewarding and they concluded that, although their cases were strikingly similar, the differentiation of giant gastritis from malignant neoplasm was extremely difficult and at times impossible Thus in one of Schindler's (1939) patients carcinoma was wrongly diagnosed by gastroscopy, and in another an extragastric tumour could not be excluded

In treatment, severe and persistent blood loss, a rare complication exemplified in the present case justifies radical surgery but when there is no such urgency, medical treatment should first be tried Spriggs (1943) obtained relief of symptoms with objective signs of improvement by means of gastric ' self lavage " The patient drinks a pint of warm water containing a small teaspoonful of sodium bicarbonate an hour before meals, and lies down for twenty to thirty minutes first on the left side and then on the right

When operation is preferred, or " self lavage " has been unsuccessful, an extensive resection through healthy tissue, as for carcinoma, is unnecessary, because incomplete removal of the affected mucosa may be followed by spontaneous regression in the portion left behind (Grime and Whitehead 1951) In order to avoid total gastrectomy and its unpleasant sequelæ, however, it is essential to recognise giant hypertrophic gastritis before the stomach is excised

Summary

A man, aged 39, with giant hypertrophic gastritis presented with bleeding which failed to respond to conservative measures, and he was subjected to total gastrectomy

In this disorder severe hæmorrhage is exceptional and the lesion is usually mistaken for carcinoma

In treatment partial gastrectomy is preferable, but relief is sometimes obtained from gastric " self lavage "

I am grateful to Dr Donald Hunter and Mr J E Richardson for permission to publish this case and for their helpful advice and criticism, and to Dr R G F Parker for his report on the microscopical findings

FEMORAL PERIARTERIAL SYMPATHECTOMY FOR DELAYED HEALING AFTER AMPUTATION

RUSCOE CLARKE
M B E, M B Lond, F R C S
SURGEON

MARY R FISHER
M B Edin
REGISTRAR

BIRMINGHAM ACCIDENT HOSPITAL

FEMORAL periarterial sympathectomy, first described by Jaboulay in 1889 (Miles and Wilkie 1936), was brought into prominence by Leriche (Leriche and Heitz 1917, Leriche and Robineau 1927) whose original case reports suggested that it would be of value in vasomotor and trophic disturbances of the extremities Since its introduction it has been used for various conditions, including Raynaud's disease, diabetic and arteriosclerotic gangrene, chronic ulceration of the leg, frostbite, and causalgia

The results of the operation have varied, its effects are local and transitory and it has therefore fallen into disfavour

Black (1924) reported 10 cases of leprosy in which periarterial sympathectomy brought about healing of chronic ulcers and stumps after spontaneous amputation, but Bernheim (1925) reported only 4 successes in 9 cases of Raynaud's disease or thromboangiitis obliterans

Gask and Ross (1934) considered that it had a definite though limited value, and Kuntz (1946) suggested that some peripheral vasodilatation always followed the operation but that the results did not justify its continued use

Aird (1949) maintained that its only advantage was in reducing spasm after embolectomy Slessor (1953), discussing

TABLE I—DEATHS DURING AND AFTER OPERATION

Cause	No	% of all deaths	% of all cases
Operative	12	10	4
Other causes	19	16	7
General metastases	55	47	21
Local metastases	27	23	10
Unknown	6	4	2

Policy and Palliation Resections

Cases treated by lobectomy as a policy were compared with those in which the operation was dictated by expediency In the latter group fell those in which the surgeon felt that the operation of choice was pneumonectomy, but in which reasons, such as respiratory insufficiency or advanced age, justified lobectomy alone as a palliative procedure Such cases are usually recommended for lobectomy

These two groups are compared in fig 6 The 264 cases included only 49 in which the operation was considered to have been palliative As might be expected their survival rate was lower than that of cases where the operation was planned Nevertheless 33% survived for more than two years, compared with 52% of those in whom the operation was deliberate

Cause of Death

The cause of death was known with reasonable certainty in 113 of the 119 patients who died during or at any time after operation Table I shows how these deaths were distributed

The operative mortality was much lower than that in any of the series of pneumonectomy cases recently published, and a quarter of these deaths were of patients whose operation was regarded as palliative

Of the 19 deaths due to causes other than carcinoma, 4 were attributed to respiratory failure, it seems certain that had pneumonectomy been carried out on any of these patients, they would not have survived the operation The survival of this group must to some extent account for the lower mortality of lobectomy, since a large proportion of the patients who die after pneumonectomy do so as a result of respiratory failure There were 6 late deaths due to coronary thrombosis, and the other 9 patients succumbed to various other causes, including carcinoma of the bladder

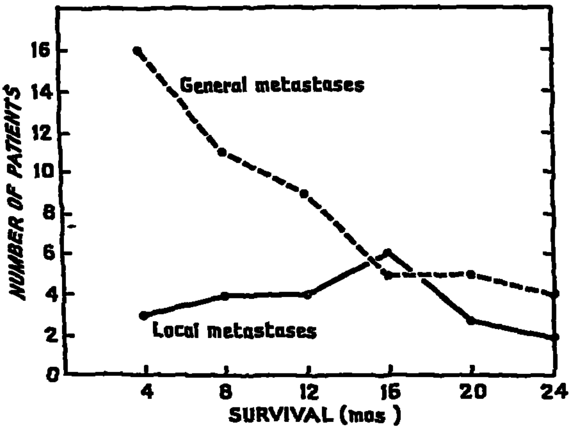

Fig 7—Time after operation at which patients died by four-month periods

Death due to Metastases

In assessing the place of lobectomy in the treatment of bronchial carcinoma it is essential to ascertain the proportion of cases in which local recurrences develop, since it may be argued that with the more limited operation this form of metastases must be more likely

In the present series the diagnosis of general metastases was based largely on clinical manifestations, and in only some of the cases was general spread confirmed at necropsy The clinical evidence of such metastases is, however, usually sufficiently strong for valid assumptions to be based upon it

The clinical evidence of local metastases is usually clearer, and it is certainly more obvious after lobectomy than after pneumonectomy, whereas after pneumonectomy a local metastasis is very unlikely to be radiographically apparent, after lobectomy the shadow cast by a local recurrence may be visible at an early stage and could seldom be missed if death were due to it

Finally in attempting to make the distinction between death from local metastases and death from general metastases, patients who were found to have secondary tumours in either lung were classed with the "local" group, whereas the 4 cases in which necropsy revealed both local and general metastases were classed with the "general" group, since each of these 4 patients died within six months of their operation

55 late deaths were attributed to general metastases, and 27 to local metastases Thus 47% of the 119 patients who died were almost certain to have done so whatever form of resection had been carried out In those whose death was due to general and to local metastases, glandular involvement was found as follows

	Glandular involvement	
	55 deaths from general metastases	*27 deaths from local metastases*
Present	21	9
Absent	34	18

There is little difference between the two groups

The fact that so many of the patients with *general metastases* died within such a short time after the operation is strong evidence that the secondaries were already present at the time Fig 7 shows the period after operation at which these patients died, compared with similar figures for those who succumbed to local metastases The figures show a close resemblance to those of Aylwin (1951), whose cases had been treated by pneumonectomy

Of the patients who died of general metastases, 36% did so within a year of operation, and 90% within two years Ochsner et al (1948) pointed out that if a patient survived for two years after a resection for carcinoma, he had a very good chance of living for five years, this fact is amply borne out by these figures, and for this reason the results of different methods of treating bronchial carcinoma should not be compared until at least two years after operation

Of the 119 patients who have died since their operation, 27 succumbed to *local metastases*—that is, 10% of the whole series The period of survival was different from that of the patients who had more widespread secondaries in that the deaths were more evenly spread over the first two years (fig 6), reaching a small peak at sixteen months Possibly if a more radical removal of the glands had been undertaken some of these patients might have survived, but nevertheless the smallness of the proportion who died from this cause, and its close correspondence to that in the series of pneumonectomies described by Aylwin (1951), suggest that there are no grounds for rejecting lobectomy on this count

Patients with pulmonary secondaries were a particularly interesting subgroup of those with local metastases In all there were 12 such cases, and, although no comparative figures are available, my impression is that this occurrence is rare after pneumonectomy Of the 12, 3 are still alive, 1 after removal of a secondary from the other lung In 6 cases there was recurrence on the same side as the original operation, and in 3 of these there were also secondaries on the other side, these cases are easily accounted for by retrograde lymphatic spread, or by the fact that tumour tissue was left behind in the residual lobe The other 6, where the recurrences were on the side opposite to that of the operation, are less easy to explain, in each of these cases the tumour was the local functioning of the vascular tree Gerard (1951) showed that an important feature of the pathogenesis of causalgia is an over-all decrease of sensory stimuli and a resultant neural imbalance Something of this nature may take place in vascular lesions, and local sympathectomy may act in a way similar to many sympathetic blocks by changing the balance of neural activity at various levels rather than by a more mechanical or local effect

Summary

In 2 cases of arteriosclerotic gangrene where healing had not followed mid thigh amputation, perifemoral sympathectomy was performed at a further operation, which led to healing

These cases are a reminder of the occasional usefulness of periarterial sympathectomy, an operation which is usually regarded as out of date

We are indebted to Dr S Sevitt and his laboratory staff for the pathological reports One of us (M R F) was in receipt of a full time grant from the Medical Research Council

Preliminary Communication

THE FATE OF ^{32}P-LABELLED BACTERIAL LIPOPOLYSACCHARIDE IN LABORATORY ANIMALS

RAPID changes in the resistance of laboratory animals to experimental infections can be produced by the injection of the lipopolysaccharide fraction of endotoxins extracted from gram-negative bacteria [1–3] It has been suggested that these lipopolysaccharides contain the substrate for the bactericidal property of the serum [1, 3]

To study the nature of this reaction further we labelled lipopolysaccharide with radioactive phosphorus (^{32}P) as an integral part of the macromolecule and found that fresh serum from various animals can liberate phosphate from this material While attempting to define more precisely the rôle of these materials in modifying the level of non specific immunity, we also studied the fate in mice and guineapigs of the ^{32}P after intravenous injection of this lipopolysaccharide

MATERIALS AND METHODS

Preparation of Radioactive Lipopolysaccharide

Escherichia coli 2380 was grown on the minimal medium of Davis and Mingioli [4] containing 1% Difco casamino-acids and in which the phosphate had been replaced by 10 mC of ^{32}P per litre in the form of carrier-free sodium phosphate The 1% casamino acid contained sufficient extraneous inorganic phosphate to satisfy the growth requirements of the organism Radioactive lipopolysaccharide was extracted from the bacteria by the phenol/water method of Westphal et al [5] The final material was entirely nondialysable and had a counting rate of 2000–2500 per µg a minute

For the in vitro experiments a small 'Perspex' dialysing cell was used The mixture of 10 µg of radioactive lipopolysaccharide and serum dilution (1 2 ml) was separated from a physiological-saline solution (2 4 ml) by a 'Cellophane' dialysing membrane, and an outlet tube from each chamber permitted 0 1 ml samples to be withdrawn at intervals for assay of ^{32}P

In the in vivo experiments all the animals were injected intravenously, mice (weighing 20–22 g) into a tail vein and guineapigs (weighing about 350 g) into a saphenous vein Blood samples were removed directly from the heart, and various organs were homogenised Serum samples were placed directly on nickel planchettes, and blood or organ homogenates were absorbed by filter-paper discs stuck on the planchettes by shellac and dried by heating from above All the specimens were counted under a thin mica end-window Geiger counter for such a time that the probable error of counting did not exceed 5%

RESULTS

In vitro

Incubation at 37°C of radioactive lipopolysaccharide with sera from several common laboratory animals and with human sera rapidly liberated dialysable phosphate This activity appeared to be greatest in rats and mice and least in rabbits

Heating of the sera at 56°C for 30 minutes abolished this activity, hæmolytic complement did not appear to be necessary, since mouse serum, which contains none, was highly active The removal of divalent cations by ethylene diamine tetra acetic acid (E D T A) greatly reduced this activity The optimal pH was about 8 Although this phenomenon has the characteristics of a phosphatase reaction, there was no obvious correlation with the content of alkaline phosphatase in the sera measured by the King Armstrong method

In vivo

When 5–60 µg of lipopolysaccharide labelled with ^{32}P was injected intravenously into mice or 100 µg into guineapigs, a large proportion was rapidly removed from the blood about 40% disappeared within the first minute, and 60–75% was eliminated from the circulation in 8 minutes Thereafter the remaining 25–40% persisted in the blood during the next hour without very appreciable diminution The distribution of radioactivity in the body showed, as might be expected, that this material is taken up by the reticulo endothelial system This was confirmed by autoradiography At least half of the removed radioactive lipopolysaccharide appeared in the liver and spleen, and smaller amounts were detected in the lungs, adrenal glands, and kidneys The absence of radioactivity from brain tissue showed that this large molecule cannot cross the blood brain barrier The highest level of radioactivity attained by the reticulo endothelial system developed within 15 minutes of injection

The third of the originally injected radioactive lipopolysaccharide which is not removed by this macrophage activity did not appear in the circulating leucocytes but remained in the plasma in a non dialysable form and was only gradually eliminated Thus 17–22% still persisted after 6 hours, 10% after 24 hours, and 2% after 48 hours A constant level of radioactivity was maintained in the liver throughout this period of gradual elimination from the plasma During the same time, however, radioactive dialysable phosphate was detected in the urine, appearing as early as 15 minutes after injection, and continued until the radioactive lipopolysaccharide had virtually disappeared from the blood

THAT assessment of the benefit resulting from operations for portal hypertension presents a difficult problem is evident from the widely divergent views (Blakemore 951, Witts 1953) The reasons for this difficulty lie in he composite nature of the disorder when it is associated with hepatic disease Some of these reasons are illustrated by the following brief case records

Case 1 —An elderly man was seen for another condition 26 years after splenectomy elsewhere for hæmatemesis and ‘Banti's syndrome” Bleeding had recurred at intervals for [illegible] years after the operation, but he had remained symptom-free during the succeeding 21 years (Learmonth 1951)

The point illustrated by this case is that the bleeding vessels in the œsophagus or their feeders may undergo spontaneous obliteration

Case 2 —A woman, aged 27 years, experienced three episodes of hæmatemesis during the 6th year after a severe and prolonged attack of toxic hepatitis Splenectomy, left nephrectomy, and splenorenal anastomosis (end to end, using a ‘Vitallium’ tube) were performed in December, 1946 She married and lived a normal life for 7½ years There was mild melæna in October, 1952, and more severe bleeding which led to her death in August, 1954 Necropsy showed that the anastomosis had been occluded for a long time

Evidently there may be complete freedom from symptoms for many years after a technically imperfect operation

Case 3 —A girl, aged 8 years, underwent splenectomy at the hands of the late Sir David Wilkie in 1934. The liver was noted to be cirrhotic. In 1954 she was seen again because of hæmatemesis which, it was learned, had recurred frequently in the intervening 20 years.

Repeated hæmatemesis is apparently not incompatible with long survival even in patients known to have hepatic disease

These examples indicate the need for a long follow-up of many cases in order to assess accurately the value of surgical treatment in portal hypertension However, such is the interest of this condition that we believe it justifiable to review now the progress of 64 cases of intrahepatic portal obstruction treated in the professorial surgical unit of the Royal Infirmary of Edinburgh during the 8 years up to the end of 1953 68 operations were performed on these patients, as follows portacaval anastomosis, 7, splenectomy and splenorenal anastomosis, 19, splenectomy alone, 27, limited œsophagogastrectomy, 8, splenic arterial ligature, 4, other operations, 3

Criteria for Assessment

We have accepted four criteria for assessing the effectiveness of operations in portal hypertension (1) a substantial reduction after operation in the incidence and severity of bleeding from varices in the lower œsophagus and the fundus of the stomach, (2) no demonstrable adverse effect on metabolic functions, and in particular on hepatic function, (3) improvement in the blood picture, and (4) improved chances of survival

Incidence of Hæmorrhage

There is no conclusive evidence on this point, because the incidence, severity, and effect of hæmorrhage in chronic hepatic disease are unpredictable and control figures from medically treated patients are concerned with mortality only In about 40% of reported cases the hæmorrhage is terminal (Ratnoff and Patek 1942, Reynell 1951), and a further 30% die within a year of the first hæmatemesis These are, in general, cases with severe hepatic damage The remaining 30% form a group in which hepatic disease may not even be suspected till hæmatemesis occurs

TABLE I—INCIDENCE OF GASTRO ŒSOPHAGEAL BLEEDING AFTER OPERATION IN PORTAL HYPERTENSION DUE TO HEPATIC DISEASE

Operation	Cases with preoperative bleeding		Cases without previous bleeding	
	No	No with postop bleeding	No	No with postop bleeding
Portal-systemic venous anastomosis	22	10	4	0
Splenectomy	15*†§	11	12	2
Splenic arterial ligation	2*‡	2	2	1
Œsophagogastrectomy	8†‡§	0		
Other			3	0
Total	47	23	21	3

* † ‡, § = 4 patients common to two categories

The incidence of bleeding after operation in the present series is shown in table I, from which the following conclusions are drawn

1 Bleeding after operations for portal hypertension occurred much more frequently in patients who presented with hæmatemesis, irrespective of the operation performed

2 After splenectomy alone the incidence of bleeding was very high when hæmatemesis had been a presenting feature, and was low if alimentary hæmorrhage had not been detected before operation. Similar results have been recorded by Pemberton and Kiernan (1945) The reason for this difference appears to be that once the anatomical pattern of the collateral circulation has been established in portal hypertension, it does not change (Macpherson 1953)

3 *In only 1 of the 10 cases with bleeding after portal systemic venous anastomosis* was the anastomosis observed to be patent, in 5 it was seen at necropsy to have been occluded, in 4 its condition was not known, but as 3 of these were splenorenal anastomoses performed with a *vitallium* tube they probably did not remain patent In 1 of these 4 cases the bleeding was from an eroded artery in an acute gastric ulcer and was not attributable *to* the portal hypertension.

4 The recurrence of bleeding after operation was as *variable and unpredictable* as in the cases treated medically The earliest onset was in the immediate post operation period and the longest interval was 6 years

5 Splenic arterial ligature has proved ineffective in preventing further hæmatemesis, but there has been no recurrence of bleeding over periods of up to *2 years after limited* œsophagogastrectomy. Because the follow-up is so brief, this statement must be regarded as a progress report only.

Hepatic Function

In a report on hepatic function *after* operations for portal hypertension (Macpherson et al 1954) we showed that (*1*) diversion of the portal blood stream from the

Systemic Associations and Treatment of Skin Diseases

KURT WIENER, M D, dermatologist, Mount Sinai Hospital, Milwaukee, Wisconsin London Henry Kimpton 1955 Pp 556 £6 6s

DR WIENER'S earlier book, published in 1947, was devoted to the skin manifestations of internal disorders *In this complementary volume he describes what is known of the internal derangements associated with dermatoses* He has done an enormous *amount* of work, and the text has no less than 2759 references from all over the world

The first few chapters are absorbing, but they are on diseases which *might* well be classified as internal or general rather than dermatological Interest flags as the dermatoses give a grudging yield of features of general interest The second half of the book, dealing with systemic treatments, is equally encyclopædic but the arrangement and selection of material is often uncritical The *final chapter* is about unorthodox treatments, which to the innocent inquirer *may seem* just as appropriate as many of the empirical remedies in the preceding chapters

Expensive, extensive, exhaustive, and exhausting

Peripheral Vascular Disease

A J BARNETT, M D, M R C P, assistant director, Alfred Hospital Clinical Research Unit, Melbourne, J R E FRASER, M D, M R A C P, sometime registrar of the unit Melbourne Melbourne University Press *London* Cambridge University Press 1956 Pp 210 *57s 6d*

THIS book is based on the monograph successfully submitted by Dr Barnett and Dr Fraser for the Stawell memorial prize essay for 1952 Its declared purpose is to present a "practical approach" to the problem of vascular disease of the extremities

A brief *survey* of the historical development of the *subject* introduces a review of vascular physiology An account of methods of diagnosis, particularly venous plethysmography, *and the pathology of common diseases* is *followed by a discussion of* clinical features and treatment The book does not set out to be an encyclopædia of vascular diseases and *the authors concentrate on the common lesions*, which they *present* with *a* good number of case histories There is much *to* recommend such an approach, but it is surprising that a "practical" book *should devote ten pages to the physics of* blood flow and only five lines to the clinical *aspects of* peripheral emboli Some lack *of* balance is also noticeable in the chapter on *treatment*, in which *surgery does not receive* enough attention

Despite these *reservations*, there is much to admire in this useful book

Die Überfunktion der Nebennieren

RUDOLF CHWALLA Vienna Maudrich *1955* Pp 330 £14 *2s*

THE large necropsy material of the distinguished Viennese pathologist, A Priesel, has been the basis of this monograph Its leading idea is the functional *entity* of the adrenal gland and the identical pathology of "hyperadrenalism," whether the cortex or the medulla or both are enlarged

Some diseases *and types of constitution* are said to be associated with *enlarged adrenals* the diseases include arteriosclerosis, hypertension, arteriolosclerotic contracted kidney, diabetes obesity, pulmonary emphysema, malignant growths (particularly carcinoma of the prostate), urinary bladder, and bronchus, and primary carcinoma of the liver *As for physique*, enlarged adrenals are found mainly among pyknic individuals

The hilar cells of the ovary (as androgen secreting elements) *and the rete ovarii* are discussed in detail Dr Chwalla notes the occurrence of eosinophil hyperplasia of the pituitary and eosinophil adenoma in conditions usually associated with *basophil hyperplasia*

Unfortunately there is no proper statistical analysis of the material nor does the writer say how the increase of cortical *or medullary* tissue was ascertained An intense yellow colour in the adrenal cortex was often taken to mean large amounts of lipids and hence hyperfunction, even without *enlargement* of the cortex In view of the rapid turnover of corticoids, this view will be accepted by few pathologists

Some of the arguments against the functional entity of the adrenals—for example, the hyperproduction of a single one of its *hormones, sometimes* with depression of another one, and the beneficial effects *of cortisone* in the adrenogenital syndrome —are not given sufficient prominence

One in Six

An Outline of the Cancer Problem I HIEGER, D SC, Royal Marsden Hospital, *London* London Allan Wingate 1955 Pp 80 12s *6d*

WRITTEN for the layman, this short book should acquaint him *with the* nature, scope, and *prospects of* cancer research at the present time Dr Hieger describes, with the authority of *an expert, the* extent and character of the problem, the ways of tackling it, statistical and *experimental*, and the current state of knowledge, and *he* indicates the possible or probable lines of advance The immense complexity *of the subject*, on the one hand, and the industry and ingenuity of those attacking it, on the other, are well illustrated Among the more *striking chapters* are those on cancer and ageing, cancer theories, *and* "lung cancer, smoking and smoke", and there *are instructive* photomicrographs, and a useful glossary It is all excellently done

Values expressed as means ± S.D. Number of cases in italic numerals in parentheses.
P values for difference between *x* years and before operation.

The findings demonstrated that the characteristic leucopenia and thrombocytopenia were corrected only if splenectomy was included in the operation. Relief of the portal venous congestion by portal systemic venous anastomosis and other measures such as splenic arterial ligation produced no such improvement. The results of a longer follow-up in 34 patients with intrahepatic portal obstruction who were submitted to splenectomy either alone or as part of a more extensive operation show that these changes in the blood picture persist, an over-all improvement in the peripheral-blood picture, with a significant rise in all values, having been maintained in patients surviving such operations for periods up to 5 years (table IV). Correction of a leucopenia averaging 4000 white blood cells per c.mm. to a sustained count of 10,000 per c.mm. would seem an important factor in increasing the ability to combat intercurrent infections. This feature has been specifically observed in 3 patients who were subject to recurrent infections of the respiratory tract. In general the number of circulating granulocytes has tended to increase in the immediate post-operation period and the number of lymphocytes to increase subsequently, so that a year or more after splenectomy the differential leucocyte-count is similar to that found before operation but the absolute figures are greater.

The improvement in the platelet-count may also have contributed to the survival of some of the patients. Spontaneous bleeding from sites other than the œsophagus is unusual in portal hypertension, even when the platelet-count is 50,000 per c.mm. or less; but it is reasonable to assume that such a thrombocytopenia renders bleeding from œsophageal varices an even more serious hazard. We consider that correction of the thrombocytopenia should be one of the aims of operation for portal hypertension.

The hæmatological records of 8 cases in which alimentary bleeding had not been detected before operation have been abstracted from the whole group (table V). The initial leucocyte and platelet counts were depressed in these cases, but the anæmia was much less prominent. Operations, which in each case included splenectomy, corrected the leucopenia and thrombocytopenia; and though the hæmoglobin level and the erythrocyte counts rose subsequently, the increase was naturally less striking than for the whole group shown in table IV.

These observations agree with previous reports by Davidson (1934) and by us (Macpherson and Innes 1953). The balance of evidence at present suggests that in patients with intrahepatic portal obstruction the enlarged spleen plays little, if any, part in depressing the formation of erythrocytes and hæmoglobin. The anæmia probably results from a combination of causes—loss of iron and protein by alimentary bleeding, low intake and poor absorption of iron (Davidson 1934), and possibly defective utilisation because of hepatic dysfunction (Macpherson 1953). The improvement after operation in this series should probably be ascribed to the administration of adequate doses of iron, and in many of the cases to a reduction in the frequency of alimentary bleeding.

Survival

Evaluation of a method of treating a disease or one of its complications must be based on the natural history of the disease. This axiom applies especially to conditions which are the result of many different causes and which may show very varied rates of progression. Hepatic cirrhosis is such a condition. Once it has become manifest the direction and rate of change depend on many factors—perhaps in particular upon the ætiology, the response to prolonged medical treatment, and the incidence of complications. Hence, to assess the value of surgery in the treatment of portal hypertension due to hepatic cirrhosis it is essential to compare statistically the results obtained in two large groups of cases which are as nearly as possible comparable clinically and in all features of treatment other than the operation in question. Two series treated almost entirely by medical measures have been reported within the past 15 years. For purposes of comparison with the results of operation in the treatment of portal hypertension the series reported by Ratnoff and Patek (1942) is not acceptable, because in 42 of the 106 patients who experienced hæmatemesis the bleeding was a terminal event. The cases analysed by Douglass and Snell (1950) are more suitable for two reasons: (1) most of the 67 cases they report had survived their first hæmatemesis long enough to be referred to the Mayo Clinic, and (2) the medical treatment was similar to that in the Edinburgh series. In table VI the results of medical treatment in all their cases of cirrhosis and in the cases complicated by hæmatemesis are compared statistically with the results in the present series after all forms of surgical treatment, and in particular after portal systemic venous anastomosis or splenectomy alone. Survival rates have been calculated from the time the patient presented in the control series, and from the time of operation in the cases treated surgically.

The following deductions are permissible from this analysis:

1 Survival rates of all cases treated surgically are significantly better than after medical treatment (*a*) for the whole period under review and (*b*) at 1 year and 3 years after operation.

2 The survival rate in cases with hæmorrhage as a presenting symptom is just significantly better after surgical treatment at 1 year, but is not significantly better than the control series at the other periods or over all.

TABLE V—INTRAHEPATIC PORTAL OBSTRUCTION WITHOUT DETECTABLE BLEEDING: EFFECT OF SPLENECTOMY ALONE OR WITH OTHER OPERATIONS ON BLOOD PICTURE

—	Before operation	1 yr after operation
Hb (%)	87.5 ± 8.1 *(8)*	98.2 ± 6.7 *(8)* $P<0.02$
Red cells (million per c.mm.)	4.45 ± 0.30 *(7)*	4.83 ± 0.50 *(7)* $P<0.02$
White cells (thousands per c.mm.)	3.98 ± 1.9 *(8)*	11.8 ± 5.0 *(8)* $P<0.01$
Platelets (thousands per c.mm.)	118 ± 95 *(6)*	406 ± 130 *(5)* $P<0.01$

o surgery. Individual case-records often appear to ndicate unequivocal improvement after operation. It s worth recalling however that Ratnoff and Patek 1942) observed that patients with cirrhosis who survived their first hæmatemesis for 1 year had more than a 50% chance of surviving 5 years. It is against this background that the survival-rate after operation must be measured. Statistical proof of the merits of surgical treatment in portal hypertension and hæmatemesis cannot be provided for another 10 years. Longer follow-up will exclude the possibility of a fortuitous remission of symptoms coinciding with the post-operation period and will take account of the effect of the better selection and preparation for operation which have been shown by experience to be desirable.

ACETAZOLAMIDE (DIAMOX) IN THE TREATMENT OF CONGESTIVE HEART-FAILURE

T. Hanley
M.D. Lond., M.R.C.P.
LECTURER

M. M. Platts
B.Sc., M.B. Sheff., M.R.C.P., D.Obst.
J. G. GRAVES RESEARCH FELLOW

DEPARTMENT OF MEDICINE, UNIVERSITY OF SHEFFIELD

Previous clinical trials of the diuretic effect of the carbonic-anhydrase inhibitor acetazolamide ('Diamox') in heart-failure have given highly conflicting results (Belsky 1953, Friedberg et al. 1953, Counihan et al. 1954, Relman et al. 1954, Ruskin 1955, Schwartz et al. 1955).

We report here the clinical and biochemical effects of acetazolamide in the treatment and prevention of cardiac œdema in 30 patients.

Material and Methods

Of the 30 patients studied 18 had congestive heart-failure. In 15 of these we compared the diuretic effects of acetazolamide and of mersalyl. In addition 12 patients who had recovered from an attack of congestive heart-failure were treated with acetazolamide alone for continuous periods of three to sixteen months to prevent recurrence of œdema.

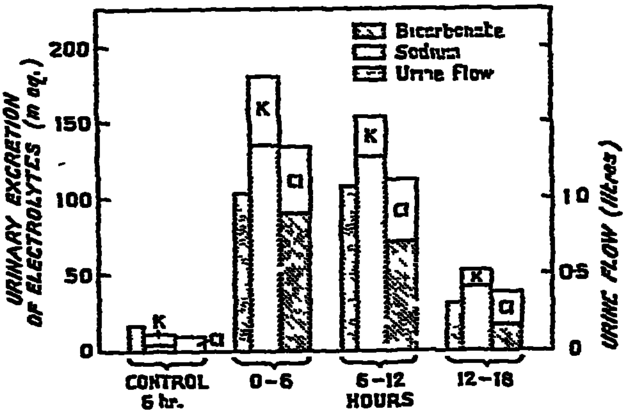

Fig. 1—Changes in urinary excretion of electrolytes and in urine flow produced by acetazolamide 0·2 g. two-hourly.

All the patients with heart-failure were treated in hospital. Their intake of water and salt was kept constant and they were weighed at the same time each day after micturition. Urine was collected under oil during the whole period of observation and was analysed for sodium and potassium by flame photometry and for chloride by electrometric titration (Sanderson 1952). The urinary level of bicarbonate was calculated by the Henderson-Hasselbalch equation after manometric estimation of the carbon dioxide (Van Slyke and Neill 1924) and measurement of the pH with a glass electrode.

Results

Changes in Urine Flow and Electrolyte Excretion Produced by Acetazolamide

Fig. 1 illustrates the changes in acid-base composition of the urine of a patient with congestive heart-failure during the first eighteen hours' acetazolamide therapy. The most striking alteration was a large increase in the excretion of bicarbonate accompanied by a raised rate of urine flow and by increased excretion of the "fixed" cations sodium and potassium. In this patient the urinary output of chloride was moderately increased, but in the great majority of patients acetazolamide caused no material alteration in the excretion of this ion. Each successive dose of acetazolamide had progressively less effect, and the composition of the urine reverted to normal after twenty-four hours in spite of repeated doses.

In 10 cases we obtained control measurements of urine flow and excretion of electrolytes for one or more days before beginning acetazolamide therapy. The accompanying table gives details of the cumulative

CUMULATIVE CHANGES IN URINARY ELECTROLYTE EXCRETION CAUSED BY ACETAZOLAMIDE

Case no.	Type of heart-disease	Daily dose acetazolamide (g.)	Water (litres)		Sodium (m.eq.)		Potassium (m.eq.)		Chloride (m.eq.)		Bicarbonate (m.eq.)

twenty-four to thirty-six hours by bilateral cortical necrosis of the kidneys in about 70% of animals. It was concluded that a single intravenous injection of toxin produced a generalised Shwartzman reaction in cortisone-treated animals. **Spain** et al[18] investigated the response to subcutaneous injection of turpentine in albino mice. Cortisone suppressed all elements of the cellular inflammatory reaction, and diffuse tissue necrosis appeared at the site of chemically induced inflammation. **Shulman** et al[19] produced localised burns in the cheek pouch of the hamster. In normal animals dilated tortuous blood-vessels ("rosette formation") were seen and healing was complete in 80% of the animals after six days; but in cortisone treated animals the rosette formation was delayed, prolonged vasoconstriction was seen, infections were common, and little or no healing was seen after as long as thirteen days. **Zweifach** and his associates have described in recent years some investigations of the inflammatory reaction to microtrauma in transparent tissues, particularly the mesentery of the rat, and the rôle of hyaluronidase, adrenaline, adrenal cortical hormones, and other factors.[20–23] Microinjection of hyaluronidase produced sudden tiny ruptures in the capillary wall, in contrast to a gradual change in endothelial permeability after mechanical or chemical microinjury. According to **Zweifach**, the inflammatory response is a complex reaction which cannot be reproduced by a single biochemical agent, either histamine or leucotaxine.

Further striking results have come from the use of the transparent chamber for the rabbit's ear. This technique which was introduced by **Sandison**[24] in 1928, has lately been improved by **Allison** et al[25] to permit observations with higher magnification and the application of a controlled thermal microinjury by a heated platinum wire. The circulatory changes followed in this way conform closely to previous findings, but new facts have been added by the study of the cellular reaction. Within a few minutes of injury, leucocytes adhere to vessel walls, at first on one side only—the endothelial surface nearest to the injury. This response may be well advanced in vessels which show no alteration of their calibre or are even constricted. Adhesion to the wall also precedes the emigration of leucocytes, and their movement is at least in the first phase, a random one without evidence of chemotaxis. After a cell has passed through a vessel wall there is apparently a defect in the endothelium, for quite often one or more cells follow exactly the same route to the perivascular tissue. The movement of leucocytes is one of active motility but the diapedesis of erythrocytes, which often leads to extensive hæmorrhage, seems to be a purely passive phenomenon. The formation of a gelatinous precipitate near the site of injury, first reported by **Zweifach**,[23] has been confirmed by a different technique. The prevention of this precipitation and the inhibition of the localised Shwartzman phenomenon by heparin, and the decrease of fibrinogen which is observed during the generalised Shwartzman phenomenon, indicate the important rôle of fibrinogen in the inflammatory response. When large doses of cortisone are given to the experimental animals before the thermal injury, a profound change takes place in the inflammatory reaction. There is evidence that the circulatory effects, such as prolongation of the ischæmic phase, are of little importance and that the main action of cortisone is exerted during the earliest stages of inflammation, thus inhibiting and delaying the adherence of leucocytes to endothelial walls and therefore their emigration and accumulation in tissue spaces. The findings suggest that cortisone has a direct action on the endothelial cells and on leucocytes, protecting them in some way against the diffusible breakdown products of tissue or plasma components.

The American Medical Student

Dr **John Ellis** prefaces his account of the American medical student[26] by an account of "medical students everywhere." Most of them, he says, are, at the time of coming to their medical school, poorly educated—not so much perhaps because they have learnt so little of the "humanities" as because of the low standard of their early scientific education. They have difficulty in realising that, despite scientific advance, medicine is still full of mysteries, and they are astonished that therapy is so often of no avail. Many are convinced that they should try to acquire the whole content of medical knowledge, and they are attracted to teachers whose didactic dogmatism makes learning a passive process. Above all, they appreciate results: they like to see the patient get better. "Hence the attraction of curative medicine as opposed to preventive; the feeling that organic disease is the really important thing; the preference for the physical sign rather than the more difficult elucidated history." Lastly, the long and sheltered years of study make them apprehensive about taking responsibility; and to devise ways in which they can be trained to do so is becoming increasingly difficult.

Beyond these universally shared qualities, Dr **Ellis** reflects upon the characteristic traits which distinguish the American student. Unlike his British counterpart, who has to "decide on medicine" at 16 and then work intensively for stiff examinations in physics, chemistry, and biology, the American student can leave his decision until he is at least 18. He gets his premedical education in a more leisurely way at college; and, though this may be of a lower academic standard, he emerges from it not only more mature but also without those bad habits of learning which are so often acquired by British students in their struggle to memorise vast quantities of facts. These college years also help to prevent mistakes in the "preselection" of students, which Dr **Ellis** regards as always more important than the much more commonly discussed selection.

The high standard required in preliminary science by British universities tends to frighten away from medicine the boy who is unaware of any aptitude

acetazolamide and shows the diminishing renal response to it in comparison with the sustained and more potent effect of mersalyl.

Prolonged "Prophylactic" Treatment of Heart-failure with Acetazolamide

12 patients who had had at least one previous attack of congestive heart-failure but were not œdematous when treatment was begun were treated with acetazolamide for continuous periods ranging from a few weeks to sixteen months. All other diuretics except 'Monotheamine' were withheld, but the amount of salt in the diet was restricted.

Of 9 patients with cor pulmonale 3 had a recurrence of heart-failure in the sixth, twelfth, and sixteenth weeks of acetazolamide therapy, the respective dosages being 500 mg. on alternate days, 250 mg. daily, and 250–750 mg. daily. When heart-failure had developed, acetazolamide was withdrawn and treatment with mersalyl was begun at once and produced a large diuresis in each case. In the remaining 6 patients with pulmonary heart-disease heart-failure did not develop during an average period of treatment of eight months.

In 2 of the 3 remaining cases severe congestive heart-failure developed in the fourth week of acetazolamide therapy; 1 of these 2 patients subsequently had a spontaneous diuresis as a result of rest in bed only, and the other had an excellent diuretic effect from mersalyl and rapidly became free from œdema.

Toxic Effects of Acetazolamide

No major toxic effects were observed. Almost all the patients who received 0·5 g. or more of acetazolamide daily became slightly drowsy and languid, and some complained of malaise, headache, and paræsthesiæ of the fingers, toes, lips, and nose. One patient developed a light-sensitive dermatitis after five days' acetazolamide therapy (0·5 g. daily). No symptoms or signs of potassium deficiency developed even in the patients treated for almost a year.

Discussion

The results agree with the opinion of Relman et al. (1954) that acetazolamide is of little value in severe congestive heart-failure due to hypertensive, ischæmic, or valvular disease. The diminishing effect of successive doses of acetazolamide has been previously described by Nadell (1953) and Friedberg et al. (1952) and was invariable in our patients; it appears to be the chief factor limiting the diuretic action of acetazolamide. The diuresis caused by acetazolamide depends almost entirely on the increased urinary excretion of bicarbonate, and the findings of Counihan et al. (1954) suggest that the diminishing renal response to acetazolamide is caused by reduction of the plasma-bicarbonate level by loss of bicarbonate in the urine. Once, therefore, maximal effect has been obtained from acetazolamide—i.e., when 150–250 m.eq. of bicarbonate has been excreted in the urine—an appropriate time must be allowed for the plasma-bicarbonate level to regain its normal value before acetazolamide will again act as a diuretic. We have found that several days are required for recovery from the effects of even a single dose of acetazolamide, and in the full cycle of treatment and recovery only about 2 litres of œdema fluid may be lost in most cases. This is a poor therapeutic result compared with the loss of several litres of œdema fluid which may follow a single injection of a mercurial diuretic. Resistance to the action of mercurial diuretics may also develop after repeated administration, but this is relatively infrequent compared with the invariable development of resistance to acetazolamide.

In a minority of patients acetazolamide causes increased urinary excretion of chloride ion as well as of bicarbonate. We observed this effect in only 3 of the 18 patients whose urinary excretion was studied in detail. In these 3 patients, 2 of whom had cor pulmonale, the increase of urine flow and of the urinary excretion of sodium was considerably greater than in the remainder, and they were the only patients on whom acetazolamide had a good therapeutic effect judged either on its own merits or in comparison with mersalyl. This finding is in agreement with the results of Schwartz et al. (1955), who deduced that the urinary excretion of chloride must have increased in their 8 patients with cor pulmonale who had a good diuresis as a result of acetazolamide therapy.

Of the 12 patients to whom we gave acetazolamide in the hope of preventing a recurrence of their previous congestive heart-failure 5 developed œdema and venous congestion while under treatment. In 6 cases with cor pulmonale heart-failure did not develop during treatment; but all of these patients concurrently restricted salt in their diet, and 4 had been free from congestive heart-failure for at least six months before treatment with acetazolamide was begun. It is therefore difficult to draw any positive conclusion about the prophylactic value of acetazolamide in these patients.

The longest interval between doses in this study was seventy-two hours and this is too short for full recovery of the plasma-bicarbonate level. It is therefore possible that a longer interval between doses might have been more effective in preventing œdema. It is highly unlikely, however, that single doses of acetazolamide at intervals of four or five days would be equally as effective as a mercurial diuretic given at similar intervals.

Summary

We describe the effects of treatment of 18 patients with congestive heart-failure with the carbonic anhydrase inhibitor acetazolamide ('Diamox').

In 3 patients acetazolamide produced a moderately good diuresis; in 10 the diuretic effect was small; and in 5 it was negligible.

The diuretic efficacy of acetazolamide was inferior to that of mersalyl in 12 of 15 patients in whom these two drugs were compared.

No serious toxic reactions were observed from acetazolamide.

In 5 of the 12 cases where acetazolamide was administered to prevent recurrence of heart-failure, œdema and venous congestion developed during treatment.

We are grateful to Prof. C. H. Stuart Harris and Dr. C. E. Davies for advice and encouragement, and Mr. A. F. Nicholls and Miss S. Exley for technical assistance. The acetazolamide was supplied by Messrs. Lederle.

"... Only now are engineers beginning to think about machines that are competent to answer 'perhaps' as well as 'yes' or 'no' or belch out strings of numbers. If I were asked—as indeed I often am—what will be the prosthetic brains of the future I should not suggest anything like the instruments of the present day; rather I should envisage some sort of 'hunch generator' that would deal speculatively with events much as I think our brains do, but would begin life as metallic meduses and would acquire human wisdom without the shocks and disappointments that, in us, breed prejudice and despair. Whether, like the legendary Medusa, they would petrify their observers, will depend on the reflective cunning of our descendants."—W. GREY-WALTER, D.SC., in *Cybernetics*. New York: Josiah Macy, jun. Foundation. 1955, p. 31.

is obvious the high-grade feeble minded person often presents a complex social and medical problem The Mental Deficiency Acts require a twofold assessment there must be medical evidence of mental defect originating before the age of 18 years, and social evidence that broadly speaking, the person in question is under one of the social disadvantages enumerated in the Acts The social criterion of unfitness for independence of one group of this high-grade class—those "found neglected"—has lately been defined by a High Court judgment reported on p 378 Before this the view was taken that a defective could be detained as "found neglected," as it were, in anticipation of social failure, but it will now be necessary to show that failure has in fact occurred and that the person is physically suffering thereby

Most of those who have to administer the law will welcome this clarification, but though the cause of individual liberty is upheld, it includes the liberty to suffer In medical terms, the symptoms of the disorder must now be manifest before treatment may be ordered this ensures that only the sick will be treated but it appears to overlook the value of prevention However, if the public accept this judgment, doctors should not object to it The fact that high grade mental deficiency, like delinquency and many other social evils, is sometimes associated with disorders which can be treated by medical means, is no reason for accepting it as an exclusively medical responsibility Just as in mental illness the community is beginning to share with the doctor the responsibility for prevention and aftercare, so this judgment may lead to an increasing awareness of the social needs of high-grade mental defectives, many of whom could be dealt with in the community if society would accept them

Annotations

MITRAL STENOSIS AND PULMONARY HYPERTENSION

THE mechanism and significance of pulmonary hypertension in mitral stenosis is not fully understood At present, the evidence suggests that it arises in at least two ways Organic narrowing of pulmonary arterioles was described at necropsy as long ago as 1936 [1], and more recently it has been confirmed in a proportion of biopsy specimens,[2] pointing to a structural cause for the increased pulmonary resistance On the other hand, the pulmonary artery pressure has been shown to rise sharply in response to exercise in severe mitral stenosis [3,4], and Davies et al [5] found that it could be considerably reduced in certain cases by giving the ganglion blocking agent, hexamethonium Since in neither circumstance did the cardiac output vary significantly, these observations suggest the presence of a reversible vasoconstriction mediated through the autonomic nervous system Whether, as Wood [6] believes, such an increased vascular resistance is a protective phenomenon guarding the lung capillaries against the consequences of a high pressure is not yet decided Davies et al questioned this view after they had reduced the pulmonary arteriolar resistance without dire results in several patients, including 2 in whom an attack of pulmonary œdema rapidly cleared after hexamethonium

Scott et al [7] have recently confirmed that the pulmonary artery pressure may be reduced by ganglion blocking drugs Their 6 patients were given tetra ethylammonium chloride (T E A C), and the pressure fell in 3 They suggest that a good response to T E A C may predict a successful result from valvotomy, and this was confirmed in 2 patients who underwent surgery, though a good result was also obtained in a patient who had not responded to T E A C The experience of Baker, Brock and Campbell [8] suggests that organic vascular changes may be reversible, for in some of their patients the pulmonary artery pressure continued to fall for as long as two years after valvotomy If this is so, preoperative assessment with T E A C or hexamethonium, although of theoretical interest, would be of little practical value, and in any case many more observations are needed Aitchison, Cranston, and Priest [9] have recently reported a rise in pulmonary-artery pressure in patients with mitral stenosis to whom they gave hydrallazine hydrochloride ('Apresoline') Since this drug lowers systemic blood-pressure, such a result was at first surprising, but it is apparently due chiefly to the tachycardia it induces It is well known that a rise in heart rate, by lessening diastole, renders pulmonary œdema more likely when there is obstruction at the mitral orifice [10] Consequently Aitchison et al warn against giving hydrallazine to patients with mitral stenosis

THE UNVACCINATED NURSE

APART from one or two steadfast opponents of vaccination, no one will deny that recent successful vaccination is efficient protection against smallpox Unfortunately, the proof is too often made plain when those unprotected by vaccination come in contact with the disease, and fall ill By no means rarely those who are at particular risk—nurses, orderlies, or domestic staff—are among the victims A recent instance was the Brighton outbreak in 1950 13 nurses and hospital domestic servants had smallpox after contact with an R A F officer who was admitted to the hospital with unrecognised smallpox His clothing was sent to a laundry, and 6 people there were also infected 5 of the hospital staff and 2 of the laundry workers died In the ward concerned, 7 of the staff were unvaccinated, and out of a total of 113 nurses and maids in this infectious diseases hospital, 27 had never been vaccinated

During the war a number of soldiers abroad died of this preventable disease, and in many cases there was no visible evidence of successful vaccination to support the written record The need for prompt revaccination of those exposed to the risk of contact was illustrated when more than 30 of the staff and patients of a general hospital overseas contracted smallpox A known case of confluent smallpox had been admitted to this hospital and imperfectly isolated, and there was some delay in revaccinating the nurses and orderlies—with the inevitable sequel Fortunately, the disease among most of the contacts was well modified, for they had been vaccinated in infancy or on joining the Army, or both

Attention has been drawn recently to the vaccination state of hospital nurses in this country The Sheffield Regional Hospital Board [11] has noted that nearly three quarters of the nurses and other hospital staff in the denum before becoming inert. If I could produce a temporary ischæmia of the gastric or duodenal lesion with a relaxation of the pyloric sphincter, the necessary conditions for the effective use of stypven might be obtained.

[11] *Sheffield Telegraph* Feb 11 1956

I recalled an incident that occurred several years previously. I had been called to deal with a case of severe and persistent hæmorrhage following gastro-enterostomy, in circumstances where neither blood nor anæsthetist were readily available. Gastric lavage produced no improvement and in desperation I injected 5 ml. of adrenaline hydrochloride (1 in 1000) down the Ryle's tube. The bleeding ceased, and to my intense relief there was no systemic reaction.

I felt that the important point was not that adrenaline had stopped the bleeding, but that it could be taken by mouth in a dosage that would have proved fatal given any other way. Stypven was similar to adrenaline in this respect; injected into the blood-stream it would be fatal, but it could be taken safely by mouth.

Dosage.—Initially a dose of 5 ml. of adrenaline and 1 ml. of stypven was given to patients who were not fit for operation. The dose was increased when I realised that both drugs could be given in complete safety, and that enough had to be given for the drugs to permeate the stomach contents and pass into the duodenum while still active. The optimum dose (which can be exceeded in perfect safety) was found to be 40 ml. of adrenaline and 5 ml. of stypven.

The use of adrenaline was at first purely theoretical, but once its safety was established beyond question, I persuaded Dr. Leitch to administer 10 ml. of adrenaline to 2 volunteers who had been referred for barium meal examination. The patients were chosen because the capacity, motility, and emptying times of their stomachs were known. Dr. Leitch reported that there was no alteration in the volume or motility of the stomach after adrenaline, but there was a complete absence of mucosal rugæ, the pylorus was fully patent, and the barium flowed rapidly into the duodenum.

The shrinkage of the gastric mucosa allows the stypven obviously easier access to the lesion, particularly a small acute erosion.

Technique

This treatment calls for the closest liaison between physician and surgeon, and I have to thank Dr. A. C. Aitkenhead for her wholehearted cooperation, and Mr. A. Tomney, who has evolved the most efficient way of using adrenaline and stypven.

Every patient admitted to the medical ward is permitted a single attack of frank hæmatemesis. If, however, he bleeds a second time while at rest in bed, a no. 10 stomach-tube is passed, usually intranasally, and the stomach is washed out with 1 pint of sterile water. 20 ml. of adrenaline hydrochloride (1 in 1000) is inserted down the tube, and the tube left in situ. After twenty minutes to half an hour, gastric lavage is repeated; a further 20 ml. of adrenaline is then injected, followed a few minutes later by 5 ml. of stypven, which is cleared from the tube by 5 ml. of sterile water.

The stomach tube is withdrawn and a slow intravenous transfusion of 2 to 4 pints of blood started. An enema is given the following morning to remove melæna, and the medical dietary regime is resumed. Dr. Aitkenhead prefers to retain the stomach-tube and aspirate at intervals to detect any fresh bleeding, but I feel that the patient is more comfortable without the tube. Any significant fresh bleeding is immediately shown by a return of pallor, sweating, a rise in pulse rate, and a fall in blood-pressure.

The most successful time to use adrenaline and stypven is immediately after bleeding has taken place. The patient is still hypotensive and, if the occluding clot is washed away, bleeding is not severe and can be controlled temporarily by adrenaline.

No amount of washing can remove large intragastric blood clots completely, and the initial dose of adrenaline occasionally acts as a mild emetic, causing the patient to vomit once and so clear his stomach. Should this not occur the interval between the first and second gastric lavages permits the greater portion of the fluid contents to pass through a patent pylorus, and the second lavage then clears what is left. The second dose of adrenaline again shrinks the gastric mucosa and permeates freely between the stomach wall and the retained blood clot. If bleeding has recurred, it is again arrested and the stypven, following the same route with little or no delay, is able to produce a stable occlusive clot over the bleeding point.

As soon as the patient recovers sufficiently, a barium meal examination is carried out. If a definite lesion is reported, he is treated by a delayed elective gastrectomy, and table II shows the low mortality-rate in 1953–54 following this form of treatment.

Treatment with adrenaline and stypven can be used in complete safety in any patient, irrespective of his age, general condition, and degree of exsanguination, and it gave such excellent results at first that I concluded that emergency gastrectomy was no longer necessary. But in 1953, 2 patients died from hæmorrhage after adrenaline and stypven, and necropsy showed that they had been bleeding from arteries of considerable size lying in the base of chronic ulcers.

Adrenaline and Stypven as "Preselectors"

It then occurred to me that these cases had been examples of "surgical" hæmatemesis, which I mentioned earlier in this paper, and that adrenaline and stypven had acted as "predictors" or "preselectors" of the patients who should have immediate operation.

If bleeding recurs within a period of seventy-two hours after the administration of adrenaline and stypven, it is proof that the patient has "surgical" hæmatemesis. It stands to reason that an occlusive blood clot in a large vessel whose walls are fixed in fibrous tissue will not withstand indefinitely the hammer-blows of a rising blood pressure, however tough the clot may be.

Should the repeated hæmorrhage be excessive and the patient collapse, adrenaline and stypven are used again but only as a preparation for operation. The drugs control the bleeding for a further period, during which time resuscitation can be achieved by rapid blood-transfusion without risk of a sudden disastrous hæmorrhage as the blood-pressure returns to normal. Adrenaline and stypven may be unnecessary in less severe degrees of bleeding. The patient should then respond satisfactorily to emergency gastrectomy: the 4 patients who had emergency gastrectomies in 1953 and 1954 were typical cases of "surgical" hæmatemesis (table II).

The knowledge that recurrent bleeding must be due to a chronic ulcer is useful if the resected portion of the stomach shows no lesion: the lesion must be in the gastric remnant, and can be looked for and dealt with accordingly.

Bleeding occasionally recurs on the fifth day after the administration of adrenaline and stypven in cases of non-surgical hæmatemesis. It seems that the underlying pathological process outlasts the period of effective control by the stypven clot. The hæmorrhage, however, is rarely severe and recovery is spontaneous.

Discussion

The advantage of this treatment is that it can be employed at the earliest possible moment in any case of hæmatemesis where a gastroduodenal lesion is suspected. It forestalls the rapid deterioration in the patient's condition caused by repeated hæmorrhage and incidentally saves a considerable amount of blood.

We found that all acute gastroduodenal lesions stopped bleeding immediately after the administration of adrenaline and stypven: adequate transfusion then ensured an uneventful recovery without further bleeding. A high proportion of chronic gastroduodenal lesions responded in the same way.

Since the adoption of the adrenaline and stypven technique, the effects of "over-transfusion" are no longer seen. The reason is that this condition only develops no financial recognition of the added responsibility of the N H S technician's work as part of a team concerned with the well being of patients The low salary at entrance is a reflection of the low educational standards which were accepted by the I M L T, but now that *these standards have been raised there are good reasons* for making the scales of junior technicians the same as those of the "scientific assistant" *grade of the Civil* Service, which would require a further increase of £80–100 a year up to the technician grade (holder of the A I M L T)

The most disappointing change in the new arrangements is the limitation of senior technicians in small laboratories to a maximum of £725 Their responsibility for other staff may be less, but their responsibility to the pathologist and to the patient is greater This limitation will increase the drift of energetic and ambitious young men to the large laboratories in the towns, leaving the equally important laboratories in country hospitals inadequately staffed, both in quantity and in quality On the other *hand, there is provision for promoting technicians who* are regularly engaged on individual work of special *difficulty*, responsibility, or *skill* as senior technician II (up to £800) *or* chief technician I (up to £900), independently of the general staffing of the laboratory If this provision can be used to upgrade technicians in sole charge of a laboratory or in charge of blood grouping and compatibility testing—who certainly undertake work of special responsibility—it may counteract to some extent the centripetal effect of the new grading

On the whole the new salary scales are reasonable, but they are not yet likely to attract many school-leavers, nor do the senior scales offer a good career in a country hospital It might be an advantage to unite the three grades senior technician I and II and chief technician I, into a single grade of supervisory technician, which would take nineteen years to climb, but which could be entered *with six or thirteen years' seniority by those appointed* to the grades now called senior technician II *or* chief technician I

ANOTHER FAMILIAL ENCEPHALITIS

WE remarked some time ago[1] on the difficulty of framing a rational classification of the different types of encephalitis in childhood Brewis[2] showed that less than a third of cases were sequels to recognised infections Classification in terms of causal agents is usually impossible, and Brewis suggested a useful symptomatic classification, but he found that nearly a quarter of his cases were too bizarre to fit into any group

A familial encephalitis *affecting 3 children of the same* parents was described by Miller and Gibbons[1, 2] in 1954 Harvey, *Haworth, and Lorber,*[4] *of Sheffield,* have *now* added a fresh syndrome to the familial group A father and 5 of his children were affected The father was mentally retarded, and he had kyphoscoliosis, choreo athetosis, and pes cavus His children fell ill in, as it were, familial epidemics characterised by fever and often by loss of consciousness After the acute illness, athetosis, hypotonia, and mental dullness remained as sequelæ The wave of acute illness recurred at least thrice After each attack *deterioration* was *evident* Very careful investigation by the Sheffield workers failed to reveal any signs of the known degenerative diseases of childhood, nor, indeed, did their special investigations reveal anything more than some non specific electro encephalographic changes

Harvey et al suggest that this syndrome may have a double ætiology the acute febrile episodes may have been attacks of viral encephalomyelitis striking down brains which were *genetically predisposed to fail* in a particular way

THE LIVER IN SARCOIDOSIS

SARCOIDOSIS is often suspected on clinical and radio*logical evidence* In the absence of a specific biochemical or bacteriological test, however, the diagnosis is finally reached by the *exclusion of other diseases,* especially tuberculosis and other varieties of granulomatosis Histological confirmation, although highly desirable, is usually lacking since it entails a *biopsy examination of* the lung or an affected and accessible lymph gland Aspiration biopsy of the liver *provides a much more* convenient method of obtaining material suitable both for microscopy and bacteriology

The first account of liver biopsy in sarcoidosis appeared in 1943[1] In the next ten years several small series were published dealing with 92 patients in 71 of whom sarcoid follicles were demonstrated in the liver Mather, Dawson and Hoyle[2] have lately recorded the most extensive and *detailed study of this kind yet published* It is based on 200 biopsies in 93 patients with the clinical and radiological diagnosis of *sarcoidosis,* in 32 with various forms *of* tuberculosis, and in 37 with miscellaneous diseases The results fully confirm the great diagnostic value of this procedure Typical lesions were found in 59 of the 93 cases of sarcoidosis The proportion with positive findings appeared to be independent of the clinical manifestations, of the tissues clinically affected or of the degree of tuberculin sensitivity A comparison of the lesions with those in tuberculosis showed that in the *absence of caseation the two are indistinguishable* Attempts to demonstrate acid-fast bacilli microscopically, by culture, or by guineapig inoculation were *also* equally unsuccessful Repeat biopsies on several patients revealed the remarkable persistence of the characteristic follicles in many cases, although sometimes clinical recovery was accompanied by complete resolution or hyaline scarring Repeat biopsies were also used to study the effect of treatment Only combined treatment with cortisone and streptomycin produced significant results in 3 out of 9 patients the lesions disappeared completely, and in the remaining 6 decrease in size or number was accompanied by fibrosis

The degree of hepatic involvement is noteworthy The estimated average number of lesions in the whole liver in the positive cases was 150,000 Despite this severe involvement there was little evidence of disturbed hepatic function Hyperglobulinæmia, when present, was more probably the result of the generalised disturbance of the reticulo endothelial-system than an indication of hepatic dysfunction Histologically, too, the liver parenchyma was normal apart from some fatty change in about 10% of cases Diffuse fibrosis, which so *often* affects the sarcoid lung was notably absent from the liver

A *comparison of the prevalence of* hepatic lesions in sarcoidosis and tuberculosis is of interest In miliary tuberculosis tuberculous lesions have been found in the liver in every one of the few cases investigated but in primary tuberculosis in only 16 out of 25 cases Thus the proportion of positive findings in sarcoidosis and primary tuberculosis is almost identical *If the two* diseases are entirely unrelated the similarity of *these figures* is remarkable Failure to demonstrate tubercle bacilli in sarcoid lesions *is the major objection to regarding* sarcoidosis as a manifestation of tuberculosis If, however, as Mather and his colleagues suggest,[2] sarcoidosis represents an exaggerated and long lasting reticulo endothelial reaction following primary tuberculosis, this criticism is largely met The chemical demonstration of specific bacterial residues in the lesions[3] would give strong supporting evidence

Summary

A case of paratyphoid-C osteomyelitis of the tibia is described Surgical drainage and chloramphenicol therapy brought about complete recovery

Attention is drawn to the occurrence of paratyphoid-C infection in West Indians

We wish to thank Mr Fulford for permission to publish this case, and Dr Taylor for her help in identifying the organism, and Miss M N Ellis for secretarial assistance

GIANT HYPERTROPHIC GASTRITIS

WITH HÆMORRHAGE REQUIRING EMERGENCY GASTRECTOMY

EIRIAN WILLIAMS
M D Lond, M R C P
SENIOR MEDICAL REGISTRAR, THE LONDON HOSPITAL

GIANT hypertrophic gastritis, a rare chronic inflammatory disease of unknown origin, is of clinical interest because it is usually diagnosed as carcinoma Its pathological features, however, are distinctive and were first described by Menétrier (1888), who termed the lesion *polyadenome en nappe* Giant hypertrophic gastritis is to be distinguished from so called chronic hypertrophic gastritis, which is often a variant of normal (Palmer 1954), and also from the polypoid lesion sometimes found in the pylorus near a peptic ulcer or the stoma of a gastro-enterostomy (Spriggs 1943)

Menetrier (1888) found that the stomach in one of his cases was

> "bulky and markedly dilated When cut, the mucosa was greatly swollen and thickened, and thrown into enormous protruding folds, the appearance resembling that of cerebral convolutions These folds were as thick as a finger, sinuous and separated by deep crypts, lying on the whole parallel to the long axis of the stomach They were particularly thick on its posterior wall, where the craters were 2–3 cms deep The hypertrophy affected the greater part of the stomach, sparing the cardia to a distance of 3 cms, and terminating abruptly in a sharp edge 8 cms from the pyloric sphincter The mucosal surface was composed of innumerable mammillations, 3–4 mms wide and 4–5 mms high, which were surrounded by small craters It was reddish violet in colour, there were many scattered ecchymoses, and the whole affected surface was covered by a thick layer of viscous mucus which was difficult to detach In section, although the hypertrophy was mainly due to thickening of the mucosa, the submucous and muscular layers and the peritoneum were also seen to be involved"

On palpation the exposed stomach has a peculiarly boggy texture, which has been likened to that of a varicocele (Bourne and Wood 1948), a bunch of fish worms (Maimon et al 1947), or, more aptly, a placenta (Strauss et al 1928), and the neighbouring lymph-glands are sometimes enlarged

The symptoms of giant gastritis are unremarkable Mild or severe dyspepsia may have been present for a few weeks or many years, while anorexia and weight loss may help to suggest the presence of carcinoma In one patient (Grime and Whitehead 1951), a firm well defined mass, which moved on respiration, emerged from beneath the left costal margin, but in all other cases nothing has been felt in the abdomen Swelling of the ankles, an unusual finding in this disorder, has been attributed to a fall in the plasma-protein level Anæmia is common, but acute bleeding has been described in only six patients (Brunn and Pearl 1926, Strauss et al 1928, Buckstein 1940, Spriggs 1943 Maimon et al 1947, Kilbourne 1953) None of these required urgent operation, but in the patient described here gastrectomy was performed for uncontrollable hæmorrhage

Case-record

A labourer, aged 39, who was admitted on Jan 12, 1955, for four years had complained of epigastric discomfort and fullness after meals, loss of appetite, flatulence, and constipation, and these symptoms were unrelieved by diet, alkaline powders, or aperients He had lost about seven pounds in weight Four weeks before admission he became tired and pale, and on one occasion he fainted at stool Twenty years and thirteen years previously he had had epigastric pain, which persisted for six months on each occasion, and while on war service in Egypt he had been ill with dysentery for three weeks His consumption of alcohol was moderate (two pints of beer on occasional weekends), and he smoked 10–15 cigarettes a day There was nothing relevant in his family history

On examination he was well nourished, anxious, and pale, and there was no œdema His pulse rate was 90 per minute and blood pressure 130/70 mm Hg No abnormal tenderness or mass was found in the abdomen His hæmoglobin was 38% and plasma proteins 6 7 g per 100 ml (albumin 4 3 g and globulin 2 4 g)

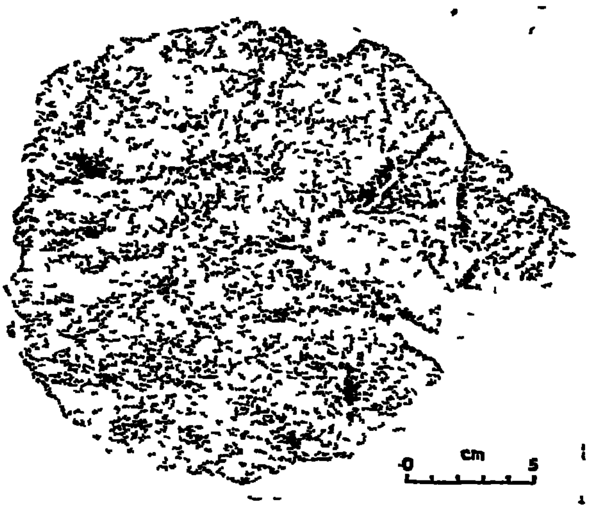
Treatment and Progress—The patient's condition improved with medical treatment and blood transfusion ($3^{1}/_{2}$ pints), and was discharged on Feb 10, four consecutive stools (Feb 8–10) containing no occult blood A barium meal examination on Feb 10 was negative

He returned on March 18, having vomited about 2 pints of blood that morning He was again pale and was moderately shocked, his pulse rate was 110 per minute and blood-pressure 90/50 mm Hg Blood was transfused, 2 pints in twenty four hours, but on March 22 his condition had not improved and a further 3 pints was given Three days later pallor was as great as on admission, and recovery with medical treatment now seemed unlikely More blood was given, and at 8 30 P M on March 25 he underwent laparotomy by Mr J E Richardson

Laparotomy and Subsequent Progress—The stomach was enlarged, and its proximal two thirds diffusely thickened, especially along the greater curve There were no palpable lymph glands Total gastrectomy and œsophagojejunostomy (Roux en Y type) were performed The patient's recovery was delayed owing to antibiotic induced staphylococcal enteritis, but he was eventually discharged in good condition Four months later he was symptom free and had almost regained his normal weight

Pathological Examination

The removed stomach showed, as was later realised, all the features of giant hypertrophic gastritis On palpation it was heavy and boggy, like a placenta, its mucosal surface



Mucosal surface of stomach

settle down to the grind for their diplomas and memberships and the like We attract a high proportion of good exam candidates (this department holds at the moment the top students of three successive years) and it *irritates* such a man to see his less gifted classmates, by mere application and tagging on to the right ski-lift of time and jobs, acquiring an ever more glittering array of letters after their names

He can, it is true, take the D C P or the D PATH of the University of London But the D C P, excellent in itself, has become too easy for those who take the Postgraduate School course and too hard for those who don't, and has ended up almost entirely a colonial preserve And I have yet to meet anyone who bothered to take the D PATH

Above that level, most people take an M D But before I come to that, let me examine the main alternatives The most important, because most often attempted, is the M R C P Now it happens that in the eyes of the Minister of Health (to whom all consultants must be Physicians, Surgeons, or Obstetricians) we count as coming under the College of Physicians, and it is therefore very reasonable of us to attempt to become members of that College But now that good anæsthetists and good theatre sisters and good transfusion services have taken most of the adventure out of surgery, and physicians have rediscovered the pleasures of research, glamour and hordes of candidates have returned to Pall Mall, and the palings that guard it have been pitched correspondingly higher

The failings of the M R C P exam as a qualification for physicians don't concern me here they are probably not very serious And even so far as the pathologist is *concerned it's not very unreasonable to ask him to* write a stiff paper in physiology and physician's medicine, and even stand his viva in them, for all medicine—all human biology come to that—is grist to his mill (he ought to be able to, and often could, make a fair stab at most of the F R C S and M R C O G papers too) But the clinical exam is another matter The ability to spot a shaded chest resonance or a glossopharyngeal paralysis or a flattened T in lead V436, or to winkle the crucial history out of a hysteric—these are not of the least importance to anyone but the practising consultant physician they are his special skill, his party trick (It would be as irrelevant to ask the physician to sort *out a really sticky* reticulosis under the microscope, or to isolate an abnormal hæmoglobin, or phage-type a few staphylococci these are *our* party tricks, but the pathologists who are graciously permitted to act as examiners for the M R C P are not tempted to introduce them to that exam)

It is true that one can be let in by the back door on submission of published work There are snags about that though There is the back door atmosphere, the *uncomfortable* implication *that one had funked the* honest examination By the time one has written enough papers *to* qualify, an M R C P is not as much use as it might have been earlier And it *is* possible to find one's submission rejected, and that is a worse blow in one's orgulous forties than in one's resilient youth (though, of course, it can be managed so that hardly anyone knows about it)

If the R C P is to be accepted as our *College*, it ought to contain more pathologists And the only proper way to this is the institution of an M R C P (PATH) But that seems improbable There is of course the M R C P (PATH) of Edinburgh but the unnatural keenness of competition among physicians has given to the Edinburgh Membership in medicine, merely because it is ever so slightly easier than the London one, an undeserved stigma as a soft option, and the reasonable and respectable pathological Membership has suffered in consequence

One comes back to the M D, and, as I said earlier most people take it But the M D is a most nebulous and unsatisfactory degree Every university is a law *to itself in the standard* it expects In at least one it can be had for little more than the asking by anyone on the teaching staff In most a thesis has to be of a remarkably low standard before it is rejected altogether Some universities demand a thesis alone, some an exam alone, some either, some both Contrast the M R C P , or even, nearer home, the M B the latter is the stiffest baccalaureate going in any university, its standard is even, and a mere pass in it is equivalent to good honours in most subjects, while the M D is in many universities the cheapest doctorate (academically cheapest, not in cash) And because nearly all M D s are tied to the M B one cannot pick and choose if the university of one's qualification offers a poor M D , one can only be content with it

It is not surprising that there is a movement towards medical PH D S One has there at least a fairly even *standard, and thesis regulations which on the whole* work well But the letters have an odd unmedical look after one's name, and except for academic appointments they probably still frighten more than attract the jungly fringes *that* still control most selection committees And there are other snags

What's to be done ? If we must have an exam, I hanker still after a London M.R C P (PATH)—with the same written paper and (within limits) viva as the physicians, but a more appropriate practical exam Failing that, a Cambridge M D or a Scottish M D at commendation level, thrown open to all comers and with free use of external examiners Or perhaps, as a last resort, a Fellowship of the Pathological Society (preferably, for ostentation, the Royal Pathological Society) with a thesis, a stiff practical exam in one elective subject, and a stiffer written *paper in medicine* as a whole This last and least likely I especially like to contemplate, for it must go without saying that all such established pillars of the society as myself would automatically (and cheaply) become Foundation Fellows

Cloud Cuckoo ? Manifestly None of these is likely to happen Yet, after all, does it matter ? For in truth, Barbara, we do not *do* so badly as we are What purpose in the last analysis, do all these exams serve ? Vain glory, and the profit of the examining bodies (who might else have to find it in even more questionable ways)—granted, but what else ? A coarse sieve for the early rejection of hopeless aspirants and a rough guide for appointment to jobs, and perhaps a stimulus to work at a critical stage of one's career—who would honestly claim more for them ? But though some *pathologists would have been better* discarded early, and some selection boards make mistakes, and some of us don't work as hard as we ought—though all these things happen, I know of no evidence that they happen more often among us than in more carefully organised trades, or that *the* adoption of a rigid exam structure would make the least difference

We have of course two things in our favour that perhaps apply rather less in other subjects *One is our* papers, of which we write more *than most people No one* worth his salt can sit daily in a pathology laboratory watching the continual pageant of the so called routine without feeling the urge to tell the world about some of it, and a pathologist who doesn't write a paper or two as often as he can can nearly always be written off And once one has committed oneself to print a few times, one is exposed for good or ill to the judgment of the discerning eye better than by all the testimonials and *degrees and certificates in the world* sympathectomy and palliative operations for occlusive arterial disease, does not mention the operation. Most workers, however, do not deny that temporary local vasodilatation follows the operation.

We report 2 cases in which femoral periarterial sympathectomy was undertaken to encourage healing in amputation stumps following arteriosclerotic gangrene.

Case-reports

Case 1.—A man, aged 76, attended the casualty department on Aug. 8, 1950, with a week's history of inflamed toes. There were sloughing ulcers on the adjoining sides of the right 4th and 5th toes and redness and swelling of the dorsum of the foot. The foot was cold, and no pulsation was felt in the dorsalis pedis, posterior tibial, or popliteal vessels. The patient was anxious not to be admitted and he was treated as an outpatient; but on Aug. 21, there was wet gangrene of the adjoining sides of the affected toes and he was admitted to hospital. His skin was otherwise healthy. Blood-pressure 210/100 mm. Hg.

Investigations.—His hæmoglobin-level was 12·6 g. per 100 ml. and white-blood-cell count 7800 per c.mm. (polymorphs 75%). Blood-urea 35 mg. per 100 ml. Urine normal.

Medical Treatment and Local Amputation.—Tolazoline hydrochloride ('Priscol') 75 mg. daily was given by mouth, and penicillin was given systemically. The inflammation subsided and the gangrenous area dried. The patient refused amputation of the leg, and local amputation was performed on Sept. 1, when it was noted that bleeding was poor. He was discharged from the ward on the 12th day after operation with no sign of healing but no gangrene.

He was readmitted three months later on Dec. 4 with spreading gangrene of the forefoot. His hæmoglobin level was then 10·1 g. per 100 ml. and this urine contained protein.

Amputation was agreed to, and was performed at mid-thigh level on Dec. 13, with penicillin and chloramphenicol cover. The wound showed no sign of healing nor of inflammatory reaction, and on Dec. 29 (the 16th postoperative day) a small area of dry gangrene appeared and this spread during the next week.

Periarterial sympathectomy was performed and the wound edges were excised and resutured on Jan. 16, 1951 (the 34th day after amputation).

Progress.—Some erythema appeared at one end of the wound on about the 6th postoperative day, but the wound had healed uneventfully by the 22nd day. The stump remained soundly healed during a 4-month follow-up and was still healed when he was admitted to another hospital 10 months later with gangrene of the other foot.

Case 2.—A man, aged 70, attended the casualty department on Feb. 20, 1955, having fallen a few days previously.

On examination there was infective gangrene of the 4th and 5th toes of the right foot, extending along the outer side of the foot to the lower leg, which was almost completely encircled by a large ulcer. Pulsation was felt in both femoral and popliteal arteries. His general condition was exceedingly poor; he was dehydrated and undernourished.

Investigations.—Radiography showed patchy calcification of the dorsalis pedis artery at the level of the tarsus. His hæmoglobin level was 14·1 g. per 100 ml. and white-blood-cell count 23,350 per c.mm. (polymorphs 87·5%).

Medical Treatment and Amputation.—The patient was admitted to hospital and given systemic penicillin and chloramphenicol and intravenous saline, plasma, and blood. On Feb. 23, a mid-thigh amputation was performed. Postoperatively his general condition improved slowly. His urine contained pus cells, red blood-cells, and occasional hyaline and granular casts, but no sugar. The stump showed no sign of healing; it was dry initially but it became moist and œdematous by the 8th postoperative day; on the 15th day, a small hæmatoma developed which increased in size and was evacuated on the 20th day. By the 30th day there was still no sign of healing. His hæmoglobin level fell from 15·0 g. per 100 ml. on Feb. 23 to 12·6 g. per 100 ml.

Periarterial Sympathectomy.—The patient was transfused with 800 ml. of blood and periarterial sympathectomy was performed on March 29 (34 days after amputation). At operation $^{3}/_{4}$ in. of the common femoral artery was stripped of its adventitia. The wound edges were excised and resutured.

Progress.—A small area of necrosis developed at the side of the stump wound with some inflammation which was maximal on about the 10th day but which improved thereafter; healing was complete by the 22nd day. Skin-temperature recordings preoperatively and on the 17th day after operation showed no significant change. After his discharge from hospital an area over the stump $^{1}/_{2}$ in. long broke down, but it healed slowly over a period of 5 weeks.

Discussion

The problem presented by these 2 patients is not uncommon. Lehman and Figueira (1953), in a review of 75 cases of arteriosclerotic gangrene treated by amputation, found delayed healing in 25 and necrosis in 15. Necrosis might be treated by reamputation at a higher level, but one is loth to take that step when mid-thigh amputation has already been done and healing may still not occur.

An alternative is to improve the local circulation sufficiently to ensure that the wound heals after simple excision and suture. In the 1st case oral tolazoline was given early without appreciable effect, thus confirming Lynn's (1950) observation in cases of occlusive vascular disease of an increased blood-flow after intravenous tolazoline, but no significant improvement after oral therapy. Lumbar sympathectomy has a more widespread and lasting effect, but this is no minor operation for the frail, elderly patient. Periarterial sympathectomy was tolerated well by both patients, and although healing was not entirely uneventful the results were very different from those of the initial amputations and it was not necessary to shorten the stump. In each case it was considered that simple excision and suture would certainly have failed.

The rationale of this operation has been the subject of considerable discussion.

The femoral artery receives its main sympathetic-nerve supply from the posterior division of the femoral nerve in a bundle which reaches the artery at the point where the profunda branch is given off. It derives a few filaments from the iliac plexus and, in the adductor canal, from the saphenous nerve and the nerve to vastus medialis (Mitchell 1953).

It is reasonable to suppose that perifemoral neurectomy will lead to dilatation of proximal vessels without necessarily affecting more peripheral vessels. The clinical effect is known to be transitory; Lambert Rogers (1931), studying the effect of this operation on chronic leg ulcers, found that healing proceeded for 5 weeks, and if the skin was healed by that time it was likely to remain so, but an ulcer still present tended to increase in size. Apparently therefore perifemoral sympathectomy will be most useful when an increased blood-supply is required in the more proximal part of the limb and when healing is likely to occur within 5 weeks of the operation. The 2 present cases satisfy both these criteria, and it can be hoped that, although the vasodilatation has subsided, the blood-supply will remain sufficient for the demands of a stump that is never likely to be submitted to the pressure of a prosthesis.

After sympathectomy there is no clear correlation between evidence of increased blood-supply and the clinical result. Indeed, in some patients with vascular insufficiency incised tissues may bleed freely yet not heal. It appears that the insufficiency is caused not only by narrowing of the blood-vessels but also by loss of their normal intermittent action and capacity to react. Experience of sympathectomy for vascular disorders has emphasised the effects of interfering with efferent nervous pathways, but the insufficiency may be caused partly by absence of normal afferent stimuli; thus sympathectomy may act not only by reducing vascular tone but also by interfering with the afferent side of the reflex arcs which control vascular function, thereby provoking a new pattern of stimulation which can alter this way, 70% survived and then underwent an anastomotic procedure to reduce the portal hypertension He favours hypotensive spinal anæsthesia during anastomotic surgery

Portal Hypertension

Dr A L DE ALMEIDA (Brazil) combined percutaneous splenoportal venography with intrasplenic manometry in assessing 97 patients with portal hypertension and in healthy subjects Of the radiographic findings in portal hypertension, he stressed the tortuosity and dilatation of the portal vein, the presence of collateral channels, and the acuteness of the angle of the portal vein with the vertebral column His measurements of the intrasplenic pressure have proved of practical importance in the diagnosis and management of portal hypertension

Bilirubin

Dr J L BOLLMAN (U S A) used the technique of reverse phase chromatography, evolved by Billing, Cole, and Lathe in England, for the identification of different bilirubins in hepatectomised dogs As would be expected, he identified indirect bilirubin in the serum In addition however, he discovered a new pigment which passes into the urine It reacts slowly in the van den Bergh reaction, although more quickly than indirect bilirubin and it is soluble in chloroform It is probably similar to pigment 1, which has been described in Great Britain

Cirrhosis with Ascites

Dr J CAROLI (France) divided his ascitic cirrhotic patients into asthenic and sthenic groups In both groups the majority of patients were alcoholics Most of the asthenic patients were female, and usually they were jaundiced, anorexic, and depressed and had lost much weight They responded badly to all forms of treatment, including diet and paracentesis abdominis The sthenic group lost their ascites in three to four weeks with multiple small paracenteses of 2-3 litres three times weekly, while receiving a 350 mg low sodium diet containing 3000 calories

Secretin Test

Dr D A DREILING (U S A) reported the results of the secretin test in 1500 patients with pancreatic and biliary tract disease *The result is abnormal in the presence of tumours* of the head and body of the pancreas Tumours of the tail of the pancreas and encroaching contiguous tumours do not affect the test It is of no practical value in the diagnosis of acute pancreatitis, because it cannot be undertaken in the acutely ill patients and it returns to normal quickly in convalescence A false positive secretin test may be obtained when the indwelling duodenal tube is displaced, so the site of this should be checked by fluoroscopy False negative secretin tests are obtained when ulcerating growths permit diversion of pancreatic secretion into sites other than the duodenum

Classification of Hepatic Cirrhosis

A special subcommittee, under the chairmanship of Dr SHEILA SHERLOCK, recommended that hepatic cirrhosis should be defined anatomically and clinically Essential anatomical features are as follows (*a*) involvement of every part of the liver, but not necessarily every lobule , (*b*) cellular necrosis at some stage of the disease , (*c*) nodular parenchymal regeneration , (*d*) diffuse fibrosis (*e*) disorganisation of the lobular architecture with connective-tissue bands uniting centrolobular zones with the portal tracts Clinically the disease is chronic and may be accompanied by liver cell failure and/or portal hypertension

The classification of cirrhosis should be morphological, ætiological, and functional Three morphological types suggested were portal, postnecrotic, and biliary , the biliary type was subdivided according to the presence or absence of obstruction of the extrahepatic biliary tract The accepted ætiological factors are malnutrition, ethyl alcohol, viral hepatitis extrahepatic biliary tract obstruction, cardiac failure, hæmochromatosis, and rarely congenital syphilis

The functional classification should include liver cell failure and portal hypertension, if either or both are present and also assessment of the activity of the disease, which indicates whether it is progressing, regressing, or stationary

It was recommended that the following terms b abolished because they are useless or confusing pseud cirrhosis, monolobular and perilobular cirrhosis, atroph and hypertrophic cirrhosis, capsular cirrhosis, fatty cirrhosis, bronzed diabetes, pigmentary cirrhosis, para cirrhosis, neoplastic cirrhosis, hypersplenomegalic cirrhosis, cirrhosis of the Banti and of the Fanconi syndrome, Hanot's cirrhosis, tuberculous cirrhosis, malarial cirrho toxic cirrhosis, alcoholic cirrhosis, and posthepatitic cirrhosis The committee excluded the last two terms not because it disagreed that ethyl alcohol and viral hepatitis are ætiological factors, but to maintain the argument that cirrhosis should be first classified morphologically, and then ætiological and functional description be added

It was urged that all physicians should test this method of classification, to determine its practicability and possible pitfalls

---

Medicine and the Law

"Found Neglected"

THE applicant was brought up in a poor law institution She was educated at ordinary schools and later employed in the institution but did not give satisfaction Once she was 17, there was no power to detain her at the institution and it was feared she might leave Therefore in June, 1948, she was removed to a mental institution under a "place of safety" order On Dec 9, 1948, magistrate made an order under the Mental Deficiency Acts 1913 to 1927 that she be detained in a mental institution on the ground that as a feeble minded person "found neglected" she was subject to the Acts There was evidence before the magistrate that she was a border line high grade mental defective After training she was allowed to live with her half-brother on licence The applicant applied for a writ of habeas corpus on the ground that she had not been "found neglected" and therefore there was no power to make the detention order The Court inquired whether there was evidence on which the magistrate could hold that the applicant was "found neglected," and the medical superintendent and the Board of Control argued that a mental defective who did not receive the special care and education which would be received in a mental institution was neglected within the meaning of the Act of 1913 and that, therefore, although the applicant was living in the poor-law institution she was "found neglected" in June, 1948 The Court reserved their judgment

Mr JUSTICE HILBERY, reading the first judgment said that the Act of 1913 did not authorise the detention of all mental defectives however circumstanced applied to persons who in addition to being defective were found neglected, abandoned, without visible means of support, or cruelly treated The words "found neglected" meant found through neglect in some degree of distress , "neglected" connoted physical suffering from a lack of essentials through want of reasonable care, and the words could only apply to a condition which was in existence, not a future condition which it was apprehended would or might come about the Mental Deficiency Act 1927, Parliament had dealt with the situation of a mental defective whose need was training which could not be provided in his home, and the local authority could not act because a defective needed care and training, but only if the parent or guardian of the defective had made a representation to the authority There was no evidence before the magistrate who made the order that the applicant was a mental defective "found neglected" and, therefore, The radioactive lipopolysaccharide removed by the reticulo endothelial cells appeared to be firmly held by them Thus only by the second day did the radioactivity of the liver begin to decrease, and a third of the original amount was still present at the end of a week One of the interesting features of the mechanism of early rapid clearance is that a constant proportion of widely varying sublethal doses of radioactive lipopolysaccharide was removed after intravenous injection That this finding does not necessarily indicate the presence of two differing substances in our material is shown by the fact that radioactive lipopolysaccharide, re extracted from the blood of guineapigs 30 minutes after injection, is treated in the same proportionate manner as the original preparation when injected into further animals

The intravenous administration of large doses of lipopolysaccharide depresses the ability of the reticulo endothelial system to remove a second injection of radioactive lipopolysaccharide 30 minutes later In some experiments the activity of the reticulo endothelial system appeared to have fallen as low as 25% of the normal This effect did not appear to depend solely on the bulk of material injected, because it required 1 mg of crude bacterial cell walls to produce the same degree of depression as 0 1 mg of purified lipopolysaccharide Furthermore, even 20 mg of trypan-blue could not depress the reticulo-endothelial system so much in half an hour

Finally, the initial clearance of radioactive lipopolysaccharide from the blood-stream by the reticulo-endothelial system is even greater in animals which had received 1–50 µg of lipopolysaccharide 48 hours previously If, however, very large doses of lipopolysaccharide were given and the animal survived, the activity of the reticulo endothelial system tended to remain subnormal after 2 days

DISCUSSION

A possibility which must be excluded is that the ^{32}P liberated from radioactive lipopolysaccharide in both the in-vitro and the in-vivo experiments was present as an impurity in the material Two findings are against this interpretation different batches of radioactive lipopolysaccharide have behaved similarly, and radioactive lipopolysaccharide re-extracted from the blood of a guineapig behaved identically with the initial material

The fate of lipopolysaccharide appears to involve two mechanisms in the animal body

(1) The reticulo endothelial system has been associated with resistance to the effects of endotoxins, for susceptibility is greatly increased after " blockading " with such substances as 'Thorotrast,' trypan blue, and colloidal iron [6,7] Further Biozzi et al [8] have shown that the ability of this system to phagocytose carbon particles can be either depressed or stimulated by the endotoxin of *Salmonella typhi* Our direct observations with radioactive lipopolysaccharide accord with the view that the reticulo endothelial cells assume a dominant part in the disposal of lipopolysaccharide

(2) The other path involves a gradual elimination of radioactive lipopolysaccharide from the plasma, one part of which (i e , $\equiv PO_4$) appears in the urine Possibly this process may be mediated by the serum phosphatase, which we have shown to be active in splitting the lipopolysaccharide in vitro The fate of the non radioactive remainder of the molecule has not yet been investigated

The toxic component of endotoxins is clearly distinct from the known phospholipid, polysaccharide, and protein fractions and contains a relatively large amount of phosphorus [9,10] The recent work of Westphal and Lüderitz [11] has characterised this substance as a second, highly insoluble, phospholipid Tal and Goebel [10] found that the toxic component was detoxified by mild acid hydrolysis, and that the only apparent change was the liberation of dialysable phosphate Whether the phosphatase reaction which we have described plays a rôle in the destruction or detoxification of living gram-negative bacteria in vivo is an important point to be determined

We acknowledge a grant towards the cost of animals from the Medical Research Council The autoradiographs were prepared by Mr A Beasley, of the pathology department, St Mary's Hospital

Reviews of Books

Body Fluids in Surgery

A W WILKINSON, CH M , F R C S E , senior lecturer in surgery, University of Aberdeen Edinburgh E & S Livingstone 1955 Pp 212 16s

THE past ten years' progress in the study of body chemistry may have been discouraging to those who have no mind for electrolytes , but no-one can deny it has been of considerable benefit to patients Inevitably the work has been reported diffusely in innumerable articles, and the assimilation of the new knowledge is made much easier by monographs on the subject This book is an outstanding example in every page there is evidence that Mr Wilkinson is a surgeon who lives and thinks in terms of body-fluids and electrolytes , the subject pours out of him without effort and with clarity, since he writes well without prolixity

The material is rationally ordered, starting with water, followed by sodium, then potassium and acid-base balance, with good descriptions of the clinical states associated with their disturbance The second half of the book deals with electrolytic imbalance associated with injury, shock, and gastro intestinal disorder, and with diseases of the heart, liver, and kidney A chapter on treatment completes it

Every surgeon will welcome this book, but it will find particular favour with those of pre-war vintage, since their training lacked an understanding of body chemistry and for them the subject is therefore harder to grasp The subject is now placed at their command in a book written by an expert to make experts

Modern Public Health for Medical Students

I G DAVIES, M D , F R C P , professor of public health and preventive medicine, University of Leeds London Edward Arnold 1955 Pp 487 30s

AUTHORS of textbooks on public health for undergraduates must make a choice Should they write a flowing, readable, and interesting narrative (an illustrated essay on the mystique of community health) and leave the student, once enthused, to extract the facts for himself ? Or should they produce a textbook giving the largest possible number of facts ? Professor Davies has chosen the latter course and produced a comprehensive and accurate textbook with all—indeed in some sections, more than all—the undergraduate needs to know about this subject

The nineteen chapters begin with a mainly historical introduction and finish with international health, accidents in the home, and health education Perhaps, as environmental sanitation is entirely omitted, a better title would have been A Textbook of Social Medicine, but within these limits the student, whether undergraduate or postgraduate, will find all he wants There are particularly good chapters on the measurement of health, diseases of social importance, and handicapped persons The index unfortunately fails to live up to the comprehensiveness of the text

In England Now

A Running Commentary by Peripatetic Correspondents

My friend Ananias failed his finals so often that we thought he'd receive his M.B. posthumously. However, once qualified he prospered steadily. Yet at this year's reunion dinner he ate two helpings of everything, touched me for a fiver, and blamed it all on a Tibetan ape.

'My brother left it with me after his last leave. Height 5 ft. 6 in., colour of hair brown, so rare that the Zoo pundits had never heard of it, and eyes like two saucers of strong tea. I was loth to harbour it. Already, because I was of non-domesticated habit, the dramatis personæ of my household came and went rapidly, and I didn't feel that an ape around the place would retard the process. But I was wrong. Obispo, as I called him, was adored by my housekeeper, and she taught him to clean shoes and lay the table. In the evenings he used to sit and watch me drink gin, and I found him a very sympathetic audience.

"One night, when Bevan's Hard Bargains had really been after their pound of flesh, I had my feet up on the mantelpiece and was giving Obispo a soul-searing account of the day. It was the look of him, sitting there gravely in my chair, chewing my stethoscope, and listening with his enormous eyes like a psychiatric consultant, that gave me the idea. If he could listen to my woes, he could listen to those of my patients.

"I gave him my cram course in medicine, and in three days he could feel a pulse and hold a pen; in five he could pretend to write, and in ten he was wearing horn-rimmed spectacles, a white coat, and a stethoscope, and taking his first surgery. He was terrific. There he sat, apparently taking notes and nodding his head solicitously. When the patient had to stop for breath, he'd gaze soulfully over his specs and loose off a sigh of sympathy that would have blown over a bus. I made up bottles of bromide and rang the changes on the colouring; for good value, I occasionally made one gently effervescent and sealed the cork with collodion, thus ensuring that the owner was clear of the premises before the explosion. The neighbourhood was awe-struck by these detonations, and decided that the Indian doctor's medicines were constructed of rare and costly 'Imalayan 'erbs.' We were really public benefactors, as everyone's neurotics assembled at our Wailing Wall.

"One day I decided Obispo had better get registered, so I cabled my brother, who sent a magnificent yakskin diploma in an obscure Tibetan dialect and four colours. It made Obispo M.D. Shangri-la, and entitled him to a salute of 21 jinghals and grazing rights for 8 yaks on the front lawn of the Great Palace at Lhasa.

'By this time, the surgery routine was running like clockwork. We'd had a few snags, of course, such as Obispo's lack of inhibitions over scratching himself, and also a little tension concerning some bananas in a patient's shopping basket. And the occasion when he drank a quart of surgical spirit and took the surgery hanging from the chandelier by his feet. However, my remarks about Yoga and the Mysterious East soon reassured the faint-hearted. More irritating to me was his trick of pointing out paragraphs in textbooks in such a way as to imply that I had made a misdiagnosis, and he took to leaving *Boyd's Pathology* about, kept open by a gin bottle at the chapter on hepatic cirrhosis. But the real trouble came while I was on holiday. Before I went, he brought me a heap of documents to sign. I learned too late that among them had been a letter he'd typed to the executive council to say I was resigning and appointing him as my successor.

'Appeal to the executive council? My dear fellow—they've just made Obispo chairman.'

* * *

When we bought our lovely old Devonshire cottage, covered in roses and creepers, I was indignant when my hard-headed lawyer brother said "all thatched houses are verminous." But I must admit that, at first, during the nervous hours of the night I used to hear sounds like outsized burglars heavily armed with coshes, tramping about under the steep-pitched roof over my bedroom ceiling. These were exterminated by lumps of bread spread with poison and thrown up through a trapdoor, and they have never returned. Then after the first autumn frosts myriads of little scampering footsteps could be heard up and down and along the alley-ways inside the old cob walls in the larder and even in the rooms. Poor dears, they met untimely deaths in traps, and now rats and mice are no more. Then I found miniature serpents climbing up the walls and even sometimes cosily tucked into blankets. I don't know what they are called and I don't need to know, because they too have disappeared.
